The use of adjunctive inhaled antibiotics in VAP has been evaluated in several studies. A systematic review of 16 observational studies and randomized trials without blinding revealed that aerosolized colistin was associated with microbial eradication (OR, 1.61; 95% CI, 1.11–2.35) and improved clinical response (OR, 1.57; 95% CI, 1.14–2.15) but the results were limited by several biases.[131] A systematic review of 12 observational and randomized trials with some blinding showed that nebulized antibiotics in patients with VAP had some benefit in patient outcomes. Nebulized antibiotics were associated with increased rate of clinical cure (RR, 1.23; 95% CI, 1.05–1.43).[132] Neither studies showed an improvement in mortality, duration of mechanical ventilation, or length of stay in the intensive care unit.

ALTERNATIVE DOSING OF ANTIBIOTICS FOR MULTIDRUG-RESISTANT PATHOGENS

Carbapenems, cephalosporins, and extended-spectrum penicillins or β-lactamase inhibitors demonstrate time-dependent killing, and it is known that bactericidal killing for these drug classes is optimized if their free drug concentrations are greater than the MIC (30%–40%, 50%–60%, and 60%–70% of the time, respectively). Prolonged or continuous infusions have been used to increase the time that free drug concentrations are greater than the MIC, theoretically leading to improved patient outcomes.[133]

Continuous infusions were first used in the late 1970s with suggested improvement in clinical cure rates,[134] but until recently they were largely abandoned owing to logistical concerns about medication stability, drug compatibility, and limited IV access. These concerns were lessened by use of contemporary prolonged infusions. This latter strategy is supported primarily by Monte Carlo simulation, a mathematical modeling technique that estimates the probability of pharmacodynamic target attainment at each MIC for a given MIC range.

Patients diagnosed with VAP and treated with cefepime (2 g every 8 hours for 3 hours) have been evaluated using Monte Carlo methodology. Investigators found that at an MIC of 1 mcg/mL, all regimens had a probability of target attainment greater than 90%. However, at an MIC of 8 mcg/mL, when compared with 30-minute intermittent infusions of 1 to 2 g every 8 hours and 2 g every 12 hours, only the prolonged infusion (3 hours) of 2 g every 8 hours maintained 90% probability of target attainment. As one might predict, this phenomenon was only demonstrated in patients with preserved renal function as defined as a creatinine clearance of 50 to 120 mL/minute.[135]

Intermittent and continuous infusion dosing strategies have also been compared when using piperacillin–tazobactam to treat Pseudomonas infections. Lodise et al.[136] retrospectively compared intermittent infusions of 3.375 g IV piperacillin–tazobactam (infused over 30 minutes every 6 hours) versus extended infusions of

3.375 g IV piperacillin–tazobactam (infused over 4 hours every 8 hours). Results indicated a shorter length of hospital stay (21 days vs. 38 days; p = 0.02) and lower 14 day mortality rate among patients with Acute Physiological and Chronic Health Evaluation-II scores >17 (12.2% vs. 31.6%; p = 0.04) in patients receiving extended infusion therapy.[136]

Ventilator-Associated Pneumonia Prophylaxis

The substantial risk of pneumonia in the ICU has prompted aggressive methods to prevent this disease.[137] The most important recommendations include the use of the semi-upright position to reduce the risk of aspiration, infection control (including hand washing) to prevent the spread of pathogens from one patient to the next, and surveillance for ICU infections.[138]

Several strategies for prevention of VAP are controversial, including selective decontamination of the digestive tract (SDD), selective oral decontamination (SOD), and topical antiseptics applied to the oral mucosa. These three strategies address the concept that VAP occurs after colonization of the upper respiratory tract. Because digestive tract flora may play a role in this colonization, the impact of various decontamination approaches has been studied. For SDD a combination therapy including topical tobramycin, polymixin E, and sometimes amphotericin B is administered to the stomach and oropharynx 4 times daily in combination with IV administration of ciprofloxacin or a second-generation cephalosporin. SOD uses a similar antimicrobial strategy to SDD, except that the IV agents are omitted and the combination therapy is applied to the oropharynx.

Historically, SDD and SOD are more widely used in Europe, and most of the literature investigating these techniques in thousands of patients and supporting their use results from outside the United States. In 2009, De Smet et al.[139] performed a large crossover study comparing standard of care ventilation bundles versus SDD versus SOD in mechanically ventilated patients and found a statistically reduced risk of 28-day mortality with an OR of 0.83 (95% CI, 0.72–0.97) for SDD and 0.86 (95% CI, 0.74–0.99) for SOD.[139]

In 2015, Roquilly et al.[140] produced the largest meta-analysis of VAP prevention techniques to decrease mortality. Over 37,000 patients were involved from 157 randomized trials. Although the overall mortality reduction was 5% in the intervention group, in a subgroup analysis, only SDD significantly decreased mortality compared to control with a RR of 0.84 (95% CI, 0.76–0.92).[140] Despite the overwhelming evidence supporting SDD, leading clinicians suggest there are still concerns of North American practitioners who fear that widespread use of antibiotics for SDD will increase antibiotic resistance and Clostridium difficile infections, particularly in the United States where drug resistance is more prevalent than in Northern Europe.[141]

Tuberculosis

Michael B. Kays

CORE PRINCIPLES	CHAPTER CASES
1 Tuberculosis is an infectious disease caused by Mycobacterium tuberculosis, and the most common site of infection is the lungs. Active disease is characterized by fever, chills, cough, night sweats, weight loss, and changes on chest radiography. Several risk factors for tuberculosis have been identified, including immune suppression, exposure to close contacts, and smoking.	**Case 68-1 (Questions 1, 2)**
2 Diagnosis of active disease includes tuberculin skin testing, chest radiography, and sputum collection for acid-fast bacilli stain and culture. Nucleic acid amplification tests and interferon-γ release assays may aid in the diagnosis of tuberculosis. Human immunodeficiency virus (HIV) screening is recommended for all patients with tuberculosis.	**Case 68-1 (Questions 3–7)**
3 The goals of therapy include cure and prevention of transmission of M. tuberculosis. Treatment of active pulmonary disease requires administration of multiple-drug therapy for a minimum of 26 weeks. Directly observed therapy is a core management strategy for all patients to ensure adherence to therapy.	**Case 68-1 (Questions 8–13)**
4 Patients should be monitored for resolution of symptoms and questioned about the occurrence of adverse events, especially hepatitis. Sputum smears and cultures should be obtained every 2 to 4 weeks initially and then monthly after cultures become negative. If treatment failure occurs, three new drugs should be added to the treatment regimen.	**Case 68-1 (Questions 14, 15)**
5 Patients with latent tuberculosis infection have a positive tuberculin skin test or interferon-γ release assay but no clinical symptoms or radiographic evidence of active disease. Isoniazid for 6 to 9 months is preferred, and rifampin for 4 months and weekly isoniazid plus rifapentine for 12 weeks are alternatives.	**Case 68-2 (Questions 1, 2)**
6 Adverse events associated with isoniazid include hepatotoxicity and peripheral neuropathy. Rifampin is associated with hepatotoxicity, flu-like syndrome, thrombocytopenia, and discoloration of body fluids. Pyrazinamide can cause hepatotoxicity and increased uric acid, whereas ethambutol can cause optic neuritis.	**Case 68-3 (Questions 1–3),** **Case 68-4 (Question 1)**
7 The case rate for tuberculosis in the elderly is greater than that in all other age-groups. Principles of treatment of tuberculosis in the elderly	**Case 68-5 (Question 1)**

	are the same as those for other age-groups.	
8	Multidrug-resistant tuberculosis can develop as a result of nonadherence to treatment. Successful treatment of multidrug-resistant tuberculosis is possible depending on the host, adherence to therapy, and the number of drugs to which the organism remains susceptible. Treatment with six to seven drugs may be required in the intensive phase.	**Case 68-6 (Questions 1, 2)**
9	HIV infection is an important risk factor for tuberculosis. The clinical manifestations in HIV-infected persons will vary depending on the severity of immunodeficiency at presentation. Principles and recommendations for treatment of active disease and latent infection in HIV-infected persons are the same as those for HIV-negative persons.	**Case 68-7 (Questions 1–3),** **Case 68-8 (Question 1)**
10	In antiretroviral-naïve patients, the optimal timing for initiating antiretroviral therapy is dependent on the patient’s CD4$^+$ cell count. Antiretroviral therapy may be delayed to decrease the potential for immune reconstitution inflammatory syndrome. If patients are receiving antiretroviral therapy, treatment of tuberculosis should begin immediately with modification of antiviral therapy as needed.	**Case 68-7 (Questions 4, 5)**
11	Treatment of active disease in pregnant women is the same as that for nonpregnant women. Pyrazinamide is not recommended in pregnancy due to insufficient safety data. The minimum duration of therapy is 9 months.	**Case 68-9 (Question 1)**
12	Infants and children have a higher risk of disseminated tuberculosis, and treatment should be initiated promptly. Ethambutol is generally avoided because it is difficult to assess visual acuity in children. Many experts prefer to initiate therapy in children with three drugs and treat for a minimum duration of 6 months.	**Case 68-10 (Question 1)**
13	Extrapulmonary tuberculosis may require longer durations of therapy. Tuberculous meningitis may require 9 to 12 months of therapy, and corticosteroids reduce sequelae and improve survival.	**Case 68-11 (Question 1)**

HISTORY

Tuberculosis (TB) is an ancient disease with evidence of spinal TB in pre-Columbian and early Egyptian remains. TB emerged as a major health problem in the 17th and 18th centuries when crowded living conditions of the industrial revolution contributed to its epidemic spread throughout Europe and the United States. Early physicians referred to TB as phthisis, derived from the Greek term for wasting, because its clinical presentation consisted of weight loss, cough, fevers, and hemoptysis. The etiologic agent was identified in 1882 when Robert Koch isolated and cultured Mycobacterium tuberculosis and demonstrated its infectious nature. With this knowledge, early treatment in the mid-1800s to the early 1900s consisted of placing patients with TB in a sanatorium for bed rest and fresh air. With the advent of radiographic film, pulmonary cavitary lesions were found to be a pivotal component in the evolution of the disease. Therapy included pneumoperitoneum, thoracoplasty, and plombage to reduce the size of the cavitary lesion, and some of these therapies are still used today for severe and refractory cases.

The modern era of medical TB therapy began in 1944 with the discovery of streptomycin and, shortly thereafter, p-aminosalicylic acid. Addition of isoniazid in 1952 and rifampin in the late 1960s greatly increased treatment success and provided hope for the eventual elimination of TB. However, multidrug-resistant TB (MDR-TB) emerged in the 1990s as a threat to the control of TB in the United States and other countries.[1–3] In the subsequent decade, published reports described the worldwide emergence of extensively drug-resistant TB (XDR-TB)[4–6] and, more recently, the emergence of totally drug-resistant (TDR) or super XDR-TB strains.[7] Because TB strains become increasingly resistant to currently available agents, the likelihood of achieving global control and elimination of this disease are diminished. Therefore, a high index of suspicion for TB, rapid pathogen identification, susceptibility testing, patient isolation, and appropriate antimicrobial therapy are critical to prevent further development and spread of drug-resistant TB.

Incidence and Epidemiology

Assuming lifelong infection, approximately 2.0 billion people (30% of the world's population) are infected with M. tuberculosis.[8] TB is the second most common causes of death from an infectious disease in the world after human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS). Globally, there were an estimated 9 million new cases of TB in 2013; the majority of these new cases were identified in the Southeast Asia, Western Pacific, and the African regions.[9] The countries with the largest number of new cases were India, China, Nigeria, and Pakistan.[9] Approximately 13% of the new TB cases in 2013 were identified in patients infected with HIV, with the African region accounting for 78% of these cases.[9] In 2013, approximately 1.1 million deaths were reported among HIV-negative cases and 0.36 million deaths were reported among HIV-positive cases.[9] These deaths include 510,000 women and 80,000 children.[9]

In the United States, 9,421 cases of TB were reported in 2014, and the incidence rate was 2.96/100,000 population, which represents the lowest recorded rate since national reporting began in 1953.[10] However, the incidence rate remained substantially higher than the national goal for elimination of TB (<1 case per 1,000,000 population).[10] Twenty-one states reported increased numbers of TB cases in 2014, and four states (California, Texas, New York, and Florida) accounted for 51% of all TB cases.[10] The number of TB cases and the incidence rates declined for both foreign-born and US-born persons, but foreign-born and ethnic and racial minorities continue to be disproportionally affected by TB in the United States. In 2014, 66% and 34% of all TB cases were reported in foreign-born and US-born persons, respectively, and the TB rate was 13 times higher in foreign-born persons compared with US-born persons (15.4 vs. 1.2 per 100,000 population).[10] Five countries accounted for more than half of TB cases in foreign-born persons: Mexico (21%), the Philippines (12%), India (8%), Vietnam (8%), and China (7%).[10] TB rates for Hispanics, non-Hispanic blacks, and Asians were 8, 8.5, and 30 times greater than the rate for non-Hispanic Caucasians.[10] Among US-born persons, the greatest number of TB cases was reported in blacks. Among persons with TB whose HIV status was known, 6% of these patients were coinfected with HIV.[10]

In the United States, 9.3% of isolates from patients with no previous history of TB were resistant to isoniazid in 2014; resistance was 7.5% in US-born individuals and 10.2% in foreign-born individuals.[10] Globally, there were approximately 480,000 cases of MDR-TB, defined as resistance to both isoniazid and rifampin, resulting in 210,000 deaths in 2013.[9] The largest number of MDR-TB cases were reported in China, India, the Russian Federation, and South Africa.[9] In the United States, 67 cases of MDR-TB were reported in 2014.[10] The overall proportion of MDR-TB cases in the United States has been stable over the last decade, ranging from 0.9% to 1.3%.[10] Foreign-born persons accounted for 85% of these MDR-TB cases.[10] The percentage of MDR-TB is approximately 7 times higher for persons with a previous history of TB compared with persons with no previous history of TB.[10] Several conditions and risk factors for persons with increased risk of infection with drug-resistant TB are shown in Table 68-1.

Table 68-1

Conditions and Risk Factors for Persons with Increased Risk of Drug-Resistant Tuberculosis

History of treatment for latent tuberculosis infection or active disease
Patients from areas with high prevalence of initial or primary drug resistance (urban population, northeast United States, Florida, California, Texas, United States–Mexico border)
Foreign-born persons from areas with high prevalence of drug-resistant tuberculosis (Southeast Asia, Mexico, South America, Africa)
Contact with persons with active infection caused by drug-resistant Mycobacterium tuberculosis
Tuberculosis in persons who are homeless, abusers of intravenous drugs, and HIV infected
Patients with positive sputum smears and cultures after 2 months of treatment

HIV, human immunodeficiency virus.

In the mid-2000s, XDR-TB emerged as another major threat to global health.[4–6] The definition of XDR-TB is resistance to isoniazid and rifampin among first-line agents, resistance to any fluoroquinolone, and resistance to at least one second-line injectable drug (amikacin, kanamycin, or capreomycin).[11] According to the World Health Organization, XDR-TB strains have been identified in 100 countries worldwide, and an estimated 9% of patients with MDR-TB have XDR-TB.[9] One of the first reports described 53 patients infected with XDR-TB from South Africa.[12] HIV status was known in 44 patients, and all of these patients were HIV positive. Fifty-five percent of the patients had no prior history of TB treatment, and 98% died with a median survival period of only 16 days after collection of the first sputum specimen.[12] In the United States, 49 cases of XDR-TB were identified between 1993 and 2006, and mortality was strongly associated with concomitant HIV infection.[13] Since 2009, 15 cases of XDR-TB have been reported in the United States, and 11 cases were among foreign-born individuals.[10]

Risk factors for XDR-TB include previous treatment for TB, HIV infection, homelessness, and alcohol use.[14] In a retrospective analysis of patients with documented MDR-TB, emergence of XDR-TB was associated with baseline chronic disease and nonadherence to MDR-TB therapy.[15] Treatment success is significantly lower for XDR-TB, and XDR-TB is associated with increased all-cause and TB-related mortality.[16] However, treatment outcomes are significantly improved when later-generation fluoroquinolones are added to the treatment regimen for XDR-TB, even if fluoroquinolone resistance was demonstrated on susceptibility testing.[17]

The evolution of TB resistance continued in 2009 with the identification of strains that were reported to be TDR, which was defined as resistance to all first-line and second-line agents.[7] Fifteen (10.3%) of 146 MDR-TB strains tested were found to be TDR-TB in Iran, and cultures remained positive in these cases after 18 months of treatment with second-line agents.[7] All of these TDR-TB cases were HIV negative. This report illustrates the critical need to develop new and effective agents for the treatment of TB caused by MDR, XDR, and TDR strains.

Etiology

TB is caused by M. tuberculosis, an aerobic, non-spore-forming bacillus that resists decolorization by acid alcohol after staining with basic fuchsin. For this reason, the organism is often referred to as an acid-fast bacillus (AFB).

M. tuberculosis is different from other bacteria in that it replicates slowly—once every 24 hours instead of every 20 to 40 minutes as with some other bacteria. The organism thrives in environments in which the oxygen tension is relatively high, such as the apices of the lung, the renal parenchyma, and the growing ends of bones.

Transmission

M. tuberculosis is transmitted through the air by aerosolized droplet nuclei that are produced when a person with pulmonary or laryngeal TB coughs, sneezes, speaks, or sings. Droplet nuclei may also be produced by other methods, such as aerosol treatments, sputum induction, bronchoscopy, endotracheal intubation, suctioning, autopsy, and through manipulation of lesions or processing of secretions in the hospital or laboratory.[18] These droplet nuclei, which contain one to three M. tuberculosis organisms, are small enough (1–5 μm) to remain airborne for long periods and reach the alveoli within the lungs when inhaled. Tubercle bacilli are not transmitted on inanimate objects, and organisms deposited on skin or intact mucosa do not invade tissues.

Several factors influence the likelihood of transmission of M. tuberculosis, including the number of organisms expelled into the air by the index patient, the concentration of organisms in the air determined by the volume of the space and its ventilation, the length of time an exposed person breathes the contaminated air, location of the exposure (small room vs. outdoors), and the immune status of the exposed individual.[19] Family household contacts, especially children, and persons working or living in an enclosed environment (e.g., hospitals, nursing homes, prisons) with an infected person are at a significantly increased risk for becoming infected. If the index case is smear positive, 50% of household contacts will have a conversion of the tuberculin skin test from negative to positive; however, if the index case is smear negative, only 5% will become infected.[19] Individuals with impaired cell-mediated immunity, such as HIV-infected persons or transplant patients, are more likely to become infected with M. tuberculosis after exposure than persons with normal immune function.[19] Travelers to TB-endemic areas with international medical exchange programs are also at risk of TB infection, regardless of involvement in direct patient care activities or duration of stay.[20]

Several techniques are effective in limiting airborne transmission of M. tuberculosis by reducing the number of droplet nuclei in a given airspace. Adequate room ventilation with fresh air is very important, especially in the healthcare setting, in which six or more room air exchanges per hour are desirable.[18],[21] New construction or renovation of existing facilities should be designed so that airborne infection isolation rooms achieve 12 or more room air exchanges per hour.[21] Ultraviolet irradiation of air in the upper part of the room can also reduce the number of viable airborne tubercle bacilli. All healthcare workers and visitors who enter the room of a patient with TB should wear at least N95 disposable respirators, and the mask should be molded to fit tightly around the nose and mouth.[21] Patients with presumed or confirmed infectious TB should wear a protective mask when being transferred to another area of the institution or after hospital discharge until they are noninfectious.[21] However, the most important means of reducing transmission of M. tuberculosis is by treating the infected patient with effective antituberculosis therapy.

Pathogenesis

LATENT INFECTION VERSUS ACTIVE DISEASE

Latent Infection

A clear distinction should be made between latent infection and active disease (tuberculosis). Latent infection occurs when the tubercle bacilli are inhaled into the body. After inhalation, the droplet nuclei containing M. tuberculosis settle into the bronchioles and alveoli of the lungs. Development of infection in the lung is dependent on the inoculum of organisms inhaled, the virulence of the organism, and the innate immune response of the host.[22–24] In the nonimmune (susceptible) host, the bacilli initially multiply unopposed by normal host defense mechanisms. The organisms are then phagocytized by alveolar macrophages and resident dendritic cells, but they may remain viable, multiplying within the cells for extended periods.[24] After 14 to 21 days of replication, the tubercle bacilli spread via the lymphatic system to the hilar lymph nodes and through the bloodstream to many other organs of the body.

Fortunately, certain organs and tissues in the body, such as the bone marrow, liver, and spleen, are resistant to subsequent multiplication of these bacilli. Organs with high blood flow and Pao_2, such as the apices of the lungs, kidneys, bones, and brain, are favorable for organism growth and may lead to extrapulmonary disease. Organisms replicate for 2 to 12 weeks until they reach a concentration of 10^3 to 10^4, plateauing coincident with the development of a T-cell-mediated immune response in the host.[24] $CD4^+$ T cells produce interferon-γ, which is an essential cytokine for activation of macrophages and mycobacterial killing, as well as other cytokines.[24] At this point, the patient has developed cell-mediated immunity, which can be detected by a reaction to the tuberculin skin test or interferon-γ release assay (IGRA), and bacterial replication is halted.[24]

In persons with intact cell-mediated immunity, activated T cells and macrophages may result in formation of a granuloma, a hallmark of TB, that is thought to represent a physical and immunologic barrier to control the infection and limit dissemination of the bacilli to the surrounding environment.[24] Cells found within the granuloma include $CD4^+$ and $CD8^+$ T cells, B cells, neutrophils, macrophages, multinucleated giant cells, and fibroblasts.[24] The organisms tend to localize in the center of the granuloma, which is frequently necrotic, and the tubercle bacilli may remain viable indefinitely within the granuloma. In addition, maintenance of the integrity of the granuloma allows for control of bacterial replication and depends on the immune status of the patient.[24] Tumor necrosis factor (TNF) is a key cytokine that is critical for the integrity of the granuloma.[25] Most patients with latent TB infection are asymptomatic with no radiographic evidence of the infection.[22] In some patients, there may be a healed, calcified lesion on chest radiograph, but bacteriologic studies are negative. A positive tuberculin skin test or IGRA is the only indication that the person has been infected with M. tuberculosis. Individuals with latent TB infection are not infectious and thus cannot transmit the organism to other individuals.[18]

Active Disease

In the majority of patients, active TB disease results from reactivation of a previously controlled latent infection, termed reactivation TB. It has been estimated that approximately 10% of individuals who acquire TB infection and do not receive therapy for the latent infection will develop active TB disease, and the risk of developing active disease is greatest during the first 2 years after infection.[18],[22],[23] In a population-based tuberculin skin test survey conducted in Florida between 1997 and 2001, the rate of reactivation with latent TB infection but without HIV coinfection was 0.040 to 0.058 cases per 100 person-years.[26] However, a recent study reported that 1 in 4 cases of active TB in the United States may be caused by recent transmission.[27] The study included patients with culture-positive TB, and the M. tuberculosis isolates were fully characterized by genotype. Clusters were defined as cases with M. tuberculosis that were an exact match by genotype within specific geospatial zones. Cases that were both genotypically and spatially clustered were considered recent TB transmission, and cases that were not genotypically and spatially clustered were considered reactivation TB. Of the 36,860 cases where genotyping was performed, 8,499 cases (23.1%) met the criteria for recent TB transmission.[27] Groups at greatest risk for recent transmission were HIV-infected individuals, members of a minority group or ethnic race, men, individuals born in the United States, children 4 years of age or younger, substance abusers, and the homeless.[27] These patients may have limited access to health care, resulting in delayed diagnosis and extended periods of infectivity.

Reactivation of TB in persons with latent TB infection is primarily a function of the immune status of the host. The ability of the host to respond to M. tuberculosis infection is reduced by certain diseases, such as diabetes mellitus, silicosis, chronic renal failure, and diseases or drugs associated with immunosuppression (e.g., HIV infection, anti-TNF-α agents, organ and hematologic transplantation, corticosteroids, and other immunosuppressive agents). The likelihood of progression from latent infection to active TB disease is greater in persons with these conditions.[22–24] HIV-infected persons, especially those with low CD4$^+$ T-cell counts, develop active TB disease rapidly after becoming infected; up to 50% of these individuals may develop active disease in the first 2 years after infection.[28] In addition, a person with untreated latent TB infection who acquires HIV infection will progress to active TB disease at an approximate rate of 5% to 10% per year.[29],[30] The relative risk for progression from latent infection to active disease is 1.6 to 25 times higher in patients treated with anti-TNF-α agents, depending on the clinical setting and the agents used.[31] Physical or emotional stress, gastrectomy, intestinal bypass surgery, alcohol abuse, hematologic disease, reticuloendothelial disease, and intravenous drug use are risk factors for development of active disease. The elderly, adolescents, and children younger than 5 years of age are also at increased risk of developing active disease.[18],[22–24,32]

Overview of Drug Therapy

Drug treatment is the cornerstone for management of patients with TB. In a patient with active TB, the overall treatment goals are to cure the individual patient and to minimize transmission of M. tuberculosis. The primary goals of chemotherapy are rapid bacterial killing, prevent emergence of drug resistance, and eliminate persistent tubercle bacilli to prevent relapse.[33] To accomplish these goals, treatment must be tailored to each patient's clinical and social circumstances to ensure adherence to and completion of treatment (patient-centered care). Effective TB treatment requires a substantial period of drug therapy, and optimization of the initial treatment phase prevents emergence of resistance and ensures success of TB therapy. Current guidelines recommend four drugs for the initial 8-week treatment phase: isoniazid, rifampin, pyrazinamide, and ethambutol.[33] The drug regimen and duration of the continuation phase depends on patient response, susceptibility of the isolate, host factors, extent of the disease (pulmonary vs. extrapulmonary), and drug tolerability.[33] The shortest duration of therapy is 6 months, but longer durations may be required with drug-resistant strains.[33] Because patients must be treated for months, directly observed therapy (DOT) is the preferred core management strategy to ensure adherence.[33–35]

In patients with latent TB infection, monotherapy with isoniazid for 6 to 9 months remains the preferred regimen although other attractive options are available.

Clinical Presentation of Active Disease

CASE 68-1

QUESTION 1: H.G. is a 35-year-old Hispanic man who presents with a 4-week history of a productive cough. The cough was initially nonproductive but became productive of yellow sputum after 2 weeks. The patient has been self-medicating with over-the-counter antitussives without relief, and he experienced hemoptysis this morning. He complains of subjective fevers, chills, night sweats, dyspnea on exertion, fatigue, and an unintentional 15-lb weight loss during the last 2 months. He immigrated to the United States from Mexico when he was 12 years old, but he has not traveled outside the United States for more than a decade. He currently works as a laborer on new home construction projects, and several of his coworkers, who moved to the United States from Mexico within the past year, have similar respiratory symptoms. He is currently married with three children. The patient has a 20-pack-year smoking history and drinks alcohol on weekends but denies illicit drug use.

On physical examination, H.G. is a thin-appearing man in mild respiratory distress. His heart rate is 94 beats/minute, his respiratory rate is 24 breaths/minute, and his temperature is 38.9°C. Bronchial breath sounds are noted in the right upper lobe on chest auscultation, and chest radiography shows extensive patchy infiltrates in the right upper lobe. Significant laboratory data include the following:

White blood cell count, 13,200/µL (72% polymorphonuclear leukocytes, 3% bands, 12% lymphocytes, 13% monocytes)
Red blood cell count, $3.7 \times 10^6/\mu L$
Hemoglobin, 11.2 g/dL
Hematocrit, 34%
Platelets, $269 \times 10^3/\mu L$
Serum electrolytes, renal function, and hepatic function are within normal limits.

He is 69 inches tall, and his weight is 68 kg. The remainder of his physical examination is unremarkable. What signs and symptoms consistent with active TB disease are present in H.G.?

H.G.'s history of cough (which gradually became productive), fever, night sweats, fatigue, and weight loss are classic symptoms of active TB.[18] Cough may be nonproductive early in the course of the illness, but with subsequent inflammation and tissue necrosis, sputum is usually produced and is key to the diagnostic studies. Sputum may contain blood (hemoptysis) in patients with advanced cavitary disease, which is particularly worrisome because cavitary lesions harbor high concentrations of organisms and the pulmonary location facilitates airborne transmission. Dyspnea is unusual unless there is extensive disease.[18] Other symptoms of TB may include pleuritic chest pain and general malaise.

In pulmonary TB, the chest radiograph usually reveals patchy or nodular infiltrates in the apical or posterior segments of the upper lobes, but changes may be observed in any segment.

The patchy infiltrates on H.G.'s chest radiograph are consistent with pulmonary TB. Cavitary lesions may be seen; however, these were absent in this patient. Moderate elevation of the white blood cell count with increased monocytes and eosinophils and anemia are the most common hematologic manifestations of TB.[18] H.G. had an elevated white blood cell count with increased monocytes, and he was also anemic.

Many patients with active pulmonary TB have no acute symptoms, and a lack of symptoms may hinder diagnosis. In one study, approximately 50% of active TB cases without classic symptoms were misdiagnosed.[36] More than one-third of the patients with active TB had no sweats, chills, or malaise, and fewer than 50% were febrile. Cough was evident in 80% of these patients, and only 25% had hemoptysis. Although dullness over the apices of the lungs and posttussive rales are expected in TB, less than one-third of these patients had any abnormal pulmonary signs. Similar findings were reported in another study.[37] Absence of specific clinical symptoms underscores the importance of skin testing, sputum smears for AFB, and chest radiographs in suspected TB. Lastly, cases of active TB are often found after routine chest radiographs for other illnesses.

Because many of the symptoms of TB also occur in persons with preexisting pulmonary disease or pneumonia, they may be overlooked and not attributed to TB.

CASE 68-1, QUESTION 2: What risk factors for TB are present in H.G.?

The close contact with his coworkers, who have similar respiratory symptoms, and their geographic origin from Mexico are risk factors for TB in H.G. In addition, studies have implicated cigarette smoking as a risk factor for TB.[38–40] In a cohort study conducted in Taiwan, smoking was associated with a twofold increase in the risk of active TB. Furthermore, a significant dose–response relationship was identified for number of cigarettes smoked per day, number of years of smoking, and number of pack-years smoked.[40] Smoking impairs mucociliary clearance, decreases phagocytic pulmonary alveolar macrophage function, decreases intracellular production of tumor necrosis factor-α, and causes iron overload in macrophages.[41–44] These defects in host defense mechanisms increase the risk of active disease after exposure to M. tuberculosis.

Diagnosis of Active Tuberculosis

CASE 68-1, QUESTION 3: A tuberculin purified protein derivative (PPD) skin test (5 test units [TU]) is ordered and placed on the volar aspect of his left arm. Sputum is collected and sent for AFB stain, culture, and susceptibility testing. His smear is positive for AFB, and the result of the tuberculin skin test, read at 48 hours, was a palpable induration of 14 mm. What is tuberculin PPD skin testing? How should the result be interpreted in H.G.?

The tuberculin skin test (Mantoux method) has been used as a diagnostic tool for infection with M. tuberculosis for decades, but a positive skin test is not necessary for the diagnosis of active TB disease. The test is frequently referred to as the PPD (purified protein derivative) test, which contains a protein prepared from a culture of the tubercle bacilli. Skin testing is performed by injecting 0.1 mL of solution containing 5 TU of PPD intracutaneously into the volar or dorsal surface of the forearm.[18],[45] The injection is made using a one-quarter to one-half-inch, 27-gauge needle and a tuberculin syringe. The solution should be injected just beneath the surface of the skin, avoiding subcutaneous tissue.[18],[46] A discrete, pale elevation of the skin (a wheal) 6 to 10 mm in diameter is produced when the injection is performed correctly. If the first injection was administered improperly, another test dose can be given at once, selecting a site several centimeters away from the original injection site.[18]

If the patient has been infected with M. tuberculosis, sensitized T cells are recruited to the skin site where they release cytokines.[47]

These cytokines induce an induration (raised area) through local vasodilatation, edema, fibrin deposition, and recruitment of other inflammatory cells to the area.[18] Typically, the reaction to the tuberculin protein begins 5 to 6 hours after injection with maximal induration observed at 48 to 72 hours. Therefore, the test should be read between 48 and 72 hours after injection because tests read after 72 hours underestimate the actual size of the induration.[18],[23] For standardization, the diameter of the induration should be measured transversely to the long axis of the forearm and recorded in millimeters.[18] The diameter of the induration should be measured and not the erythematous zone surrounding the induration.

An induration of at least 5 mm in diameter read 48 to 72 hours after injection is a positive reaction in an individual with a recent history of close contact with a person with active TB, a person with fibrotic changes on chest radiograph consistent with previous TB, organ transplant patients and other immunosuppressed patients (receiving the equivalent of ≥15 mg/day of prednisone for >1 month), or HIV-infected persons.[18],[45],[48],[49]

An induration of at least 10 mm in diameter is a positive reaction with clinical conditions associated with increased risk for TB, such as diabetes mellitus, silicosis, chronic renal failure, malnutrition, leukemia, lymphoma, gastrectomy, jejunoileal bypass, and weight loss of greater than 10% of ideal body weight.[18],[45],[49] In addition, an induration of at least 10 mm is considered to be positive in recent immigrants (<5 years) from countries with a high prevalence of TB, injection drug users, residents and employees of high-risk congregate settings (e.g., prisons, nursing homes, homeless shelters), healthcare workers, mycobacteriology laboratory personnel, and children younger than 4 years of age or infants, children, and adolescents exposed to adults in high-risk catgories.[18],[45],[49] The skin test is also considered positive for persons with an increase in induration diameter of at least 10 mm within a 2-year period.[45],[49] For individuals with no risk factors for TB, an induration of at least 15 mm is required for a positive reaction.[45],[49]

It is very likely that H.G. has been in close contact with persons with active TB, that is, his coworkers, even though they have not yet been diagnosed with active TB. When all factors are considered, the PPD of 14 mm should be considered to be positive in H.G.

CASE 68-1, QUESTION 4: Because H.G.'s PPD skin test is positive, does this confirm his diagnosis of active TB? What other laboratory tests may be performed to aid in the diagnosis of TB in H.G.?

H.G.'s positive reaction to 5 TU of PPD alone does not imply active TB disease. It only confirms that he has previously been infected with M. tuberculosis. To confirm the diagnosis of active TB disease in H.G., M. tuberculosis must be detected and isolated from sputum, gastric aspirate, spinal fluid, urine, or tissue biopsy, depending on the site of infection.[18] As was performed in H.G., detection of AFB in stained sputum smears examined microscopically should be the first test to confirm the presence of mycobacteria in a clinical specimen. It is the easiest and fastest procedure that can be performed and allows preliminary confirmation of the diagnosis. Sputum samples for AFB stain and culture are best obtained early in the morning on at least three separate days.[34] The cough reflex is usually suppressed at night, and the first early morning expectoration represents secretions accumulated in the chest overnight. The number of organisms in the morning sample is greater, and the diagnostic yield is higher. Smears may be prepared directly from clinical specimens or from concentrated preparations by placing the specimen on a glass slide under a microscope with a Ziehl–Neelsen or fluorochrome stain (not a Gram stain).[18] Sensitivity of sputum smear microscopy is low because 5,000 to 10,000 bacilli/mL of specimen must be present for AFB detection in stained smears.[18],[50] Therefore, a negative AFB smear does not rule out active TB disease, and patients with active TB and negative AFB smears may facilitate transmission of M. tuberculosis. Additional limitations of the AFB smear are its inability to differentiate among mycobacterial species and between viable and nonviable organisms. In many areas of the United States, Mycobacterium avium complex organisms are commonly isolated from the sputum of patients in whom a diagnosis of TB is highly probable, such as the elderly and patients with HIV infection.[51] This finding has resulted in a marked decrease in the specificity and positive predictive value of the sputum smear, in some cases to as low as 50%.[52]

The gold standard for laboratory confirmation of TB is culture.[53] Some patients may have a negative AFB smear, but a sufficient number of organisms may be present to produce a positive culture. Only 10 to 100 organisms are needed for a positive culture.[18] As a result of the limitations of the AFB smear, a positive culture for M. tuberculosis is necessary to definitively diagnose TB in H.G. and all patients, even if the AFB smear is positive. In addition, culture allows for genotyping and susceptibility testing of the isolate.[51] Because M. tuberculosis grows slowly (i.e., once every 24 hours), it may take several weeks for the cultures to become positive.[18] Broth-based culture systems such as BACTEC, MGIT, MB/BacT, Septi-Check, and ESP, when combined with DNA probes, can result in positive cultures in 2 weeks or less for sputum smear-positive specimens and in 3 weeks or less for smear-negative specimens.[51]

Nucleic acid amplification (NAA) tests are available to enhance and expedite direct identification of M. tuberculosis in clinical specimens independent of mycobacterial culture.[54],[55] These tests amplify the specific target sequences of nucleic acids in M. tuberculosis that can be detected by a nucleic acid probe within 24 to 48 hours. Two NAA tests are approved by the Food and Drug Administration (FDA) for use in the United States. The enhanced amplified M. tuberculosis direct test is approved for detection of M. tuberculosis in AFB smear-positive and smear-negative respiratory specimens. The sensitivity of this test is greater than 95% for patients with AFB-positive smears and 75% to 90% for patients with AFB-negative smears. The Amplicor M. tuberculosis test is approved for detection of M. tuberculosis in AFB smear-positive respiratory specimens. Sensitivity of the Amplicor test is greater than 95% for patients with AFB-positive smears and 60% to 70% for patients with AFB-negative smears. Specificity of the NAA tests is greater than 95% for both AFB smear-positive and smear-negative pulmonary specimens.

Compared with AFB smears, additional benefits of NAA testing include the ability to rapidly confirm the presence of M. tuberculosis in a majority of patients with AFB-negative smears and the positive predictive value of greater than 95% for AFB-positive specimens in settings where nontuberculous mycobacteria are common.[53] NAA tests are cost-effective because they prioritize contact investigations, improve decision making regarding respiratory isolation, and decrease unnecessary TB treatment.[56],[57] Current guidelines recommend NAA testing on at least one respiratory specimen from a patient with signs and symptoms of pulmonary TB for whom a diagnosis has not been established and for whom the test result would alter case management and infection control activities.[53] If the NAA result and the AFB smear result are positive, the patient is presumed to have TB, and drug treatment should be initiated while awaiting culture results.[53] If the NAA result is positive and the AFB smear result is negative, clinical judgment should be exercised regarding initiating drug therapy, and additional diagnostic testing may be needed. If the NAA result is negative and the AFB smear result is positive, a test for inhibitors should be performed and an additional specimen should be tested with NAA. Sputum specimens (3%–7%) might contain inhibitors that prevent or reduce amplification and cause false-negative NAA results.[53] If the NAA result and the AFB smear result are negative, clinical judgment is recommended in the decision to begin drug therapy because NAA tests lack the sensitivity in AFB smear-negative specimens needed to exclude the diagnosis of TB.[53]

CASE 68-1, QUESTION 5: Would a negative tuberculin skin test have eliminated the possibility of infection with M. tuberculosis in H.G.?

A negative response to 5 TU of PPD in H.G. would not exclude active infection with M. tuberculosis. The PPD skin test has a reported false-negative rate of 25% during the initial evaluation of persons with active tuberculosis.[18] This high false-negative rate is attributable to poor nutrition and general health, overwhelming acute illness, or immunosuppression. False-negative results usually occur in persons who have only recently been infected or are anergic. Anergy, the decreased ability to respond to antigens, may be caused by severe debility, advanced age, immaturity in newborns, high fever, sarcoidosis, corticosteroids, immunosuppressive drugs, hematologic disease, HIV infections, overwhelming TB, recent viral infection, live-virus vaccinations, and malnutrition.[18] If anergy is suspected, control skin tests (Candida, mumps, or Trichophyton) may be placed in the contralateral arm. If the control test results are positive and the PPD test result is negative, infection with M. tuberculosis is less likely. The Centers for Disease Control and Prevention (CDC) changed its recommendations regarding anergy skin testing in HIV-infected patients with a negative PPD. They cite problems with standardization and reproducibility, a low risk for TB associated with a diagnosis of anergy, and the lack of apparent benefit of therapy for latent TB infection in anergic HIV-infected patients. Therefore, the use of anergy testing in conjunction with PPD is no longer routinely recommended in this population or other patients who are immunocompromised.[48],[58],[59]

CASE 68-1, QUESTION 6: On further questioning, H.G. informs the medical team that he received the BCG vaccine when he was a child in Mexico. What is the BCG vaccine? What effect does the BCG vaccine have on the results of the tuberculin skin test? What other test may be performed in H.G. for detection of M. tuberculosis infection?

BCG, or bacille Calmette–Guérin, is a live vaccine derived from an attenuated strain of Mycobacterium bovis, and it is used in many foreign countries with a high prevalence of TB to prevent the disease in persons who are tuberculin negative. Many different BCG vaccines are available worldwide, and they differ with respect to immunogenicity, efficacy, and reactogenicity. Additional factors, such as genetic variability in the vaccinated subjects, the nature of the mycobacteria endemic in different parts of the world, and the use of different doses and immunization schedules, may contribute to the varied degrees of protection provided by the vaccine. The protective effect derived from BCG vaccines in case–control studies ranges from 0% to 80%.[60] Two meta-analyses calculated estimates of the protective efficacy of BCG vaccination for preventing TB. Results from the first meta-analysis indicated a 75% to 86% protective effect against meningeal and miliary TB in children.[61] In the second meta-analysis, the overall protective effect of BCG vaccines was approximately 50%.[62] Vaccine efficacy was higher in studies in which persons were vaccinated during childhood in contrast with those vaccinated at older ages.[62] Unfortunately, neither study could confirm vaccine efficacy for preventing pulmonary TB.

Prior vaccination with BCG usually results in a false-positive tuberculin skin test in patients who are not infected with M. tuberculosis, but skin test reactivity does not correlate with protection against TB.[18],[60] There is no reliable method of distinguishing tuberculin reactions caused by BCG vaccination from those caused by natural mycobacterial infections.[18],[60] Therefore, it is prudent to consider "positive" reactions to 5 TU of PPD in BCG-vaccinated persons as indicating infection with M. tuberculosis, especially among persons from countries with a high prevalence of TB.[18] Even though H.G. received the BCG vaccine when he was a child, the results of the PPD skin test should still be considered positive, especially in light of his symptoms.

In general, BCG vaccination is not recommended for routine prophylaxis in the United States because the risk of exposure to TB is relatively low. BCG vaccination should be considered only for very select persons who meet specific criteria and in consultation with a TB expert. BCG vaccination should only be considered for infants or children who are PPD negative and are continually exposed to a highly infectious, untreated patient with active TB or a child who is continually exposed to a person with infectious pulmonary TB caused by M. tuberculosis strains resistant to isoniazid and rifampin.[60] BCG vaccination of healthcare workers should be considered on an individualized basis in settings in which a high prevalence of patients is infected with MDR-TB, transmission of MDR-TB strains to healthcare workers and subsequent infection are likely, and comprehensive infection control precautions have been unsuccessful.[60] BCG vaccination is contraindicated in pregnancy and in persons who are immunocompromised (e.g., HIV infection) or persons who are likely to become immunocompromised (e.g., organ transplantation).[60] Adverse reactions to the BCG vaccine vary according to the type, dose, and age of the vaccine. Osteitis, prolonged ulceration at the vaccination site, lupoid reactions, regional suppurative lymphadenitis, disseminated BCG infection, and death have been reported.[60]

An interferon-γ release assay (IGRA) is preferred over the tuberculin skin test for persons who have received the BCG vaccine.[63] Two IGRAs are currently approved by the FDA as an aid for diagnosing both latent and active M. tuberculosis infection: the QuantiFERON-TB Gold test and the T-SPOT.TB test. These IGRAs assess response to synthetic peptides that represent specific proteins, early secretory antigenic target-6 (ESAT-6) and culture filtrate protein-10 (CFP-10), that are present in all M. tuberculosis strains.[63] In sensitized patients, ESAT-6 and CFP-10 are recognized by T cells and stimulate release of interferon-γ. The QuantiFERON-TB Gold test measures the interferon-γ concentrations released using an enzyme-linked immunosorbent assay. The T-SPOT.TB test uses an enzyme-linked immunospot assay (ELISpot) to detect increases in the number of cells that secrete interferon-γ. However, ESAT-6 and CFP-10 are not present in BCG vaccine strains and most nontuberculous mycobacteria; therefore, IGRAs have improved specificity in BCG-vaccinated persons compared with the tuberculin skin test.[63] Results are available within 24 hours compared to 2 to 3 days for tuberculin skin testing.

CASE 68-1, QUESTION 7: Should H.G. be tested for HIV infection?

The CDC recommends HIV screening for all patients with TB as well as those persons suspected of having TB disease and contacts of patients with TB.[64] Therefore, H.G. should be tested for HIV. HIV infection is the most important risk factor for progression of latent TB infection to active disease, and progression is more rapid in HIV-infected persons. Unlike other AIDS-related opportunistic infections, CD4 count is not a reliable predictor of increased risk of TB disease in

HIV-infected persons.[65] TB may

---

be the first manifestation of HIV infection because patients can have a relatively high CD4 count when TB disease develops.[65]

TREATMENT OF ACTIVE DISEASE

Initial Therapy

CASE 68-1, QUESTION 8: H.G.'s HIV test is negative. How should treatment be initiated in H.G., pending the results of sputum culture and susceptibility testing? Can he transmit M. tuberculosis to others during treatment?

There are four basic regimens recommended for the treatment of adult patients with active TB caused by organisms that are known or presumed to be drug susceptible (Table 68-2).[33] Because H.G. has not been treated previously for TB, he should be started on isoniazid, rifampin, pyrazinamide, and ethambutol. However, he has been in close contact with persons with symptoms resembling TB who are from an area (Mexico) with a high prevalence of drug-resistant TB. Therefore, H.G. must be closely monitored for resolution of symptoms, results of repeated sputum smears, and culture and susceptibility results, regardless of the initial treatment regimen. Previous guidelines recommended the addition of ethambutol only if the local prevalence of isoniazid-resistant M. tuberculosis is at least 4%.[34],[66] In the United States, 9.3% of M. tuberculosis isolates recovered from patients with no previous history of TB were resistant to isoniazid in 2014.[10] The prevalence of isoniazid resistance was higher in foreign-born persons (10.2%) compared with US-born persons (7.5%).[10] In patients with a history of previous of TB, 18.9% of strains were resistant to isoniazid in 2014, with 24.7% resistance in foreign-born persons versus 4.4% resistance in US-born persons.[10] Because of the relatively high likelihood of TB caused by isoniazid-resistant organisms, four drugs are necessary in the initial 8-week treatment phase.[33]

The initial four-drug regimen may be administered daily throughout the 8-week period (regimen 1), daily for the first 2 weeks and then twice weekly for 6 weeks (regimen 2), or thrice weekly throughout (regimen 3).[33] Based on clinical experience, administration of drugs for 5 days/week is considered to be equivalent to 7 days/week administration and either regimen 1 or 2 may be considered "daily." However, 5-day-a-week administration should always be given by DOT.[33] Drug dosages for these recommended regimens are listed in Table 68-3. H.G. should be started on isoniazid 300 mg daily, rifampin 600 mg daily, pyrazinamide 1,500 mg daily, and ethambutol 1,200 mg daily. He should also receive pyridoxine 25 mg/day to minimize the risk for development of isoniazid-induced peripheral neuropathy.

Table 68-2

Treatment Regimens for Pulmonary Tuberculosis Caused by Drug-Susceptible Organisms

Initial Phase			Continuation Phase			Rating (Evidence)[a]		
Regimen	**Drugs**	**Interval and Doses (Minimal Duration)**	**Regimen**	**Drugs**	**Interval and Doses (Minimal Duration)[b]**	**# Total Doses (Minimal Duration)**	**HIV–**	**HIV+**
1	INH RIF PZA EMB	7 days/week for 56 doses (8 weeks) OR 5 days/week for 40 doses (8 weeks)[c]	1a	INH/RIF	7 days/week for 126 doses (18 weeks) OR 5 days/week for 90 doses (18 weeks)[c]	182–130 (26 weeks)	A (I)	A (II)
			1b	INH/RIF	Twice weekly for 36 doses (18 weeks)	92–76 (26 weeks)	A (I)	A (II)[d]
			1c[e]	INH/RPT	Once weekly for 18 doses (18 weeks)	74–58 (26 weeks)	B (I)	E (I)
2	INH RIF PZA EMB	7 days/week for 14 doses (2 weeks) then twice weekly for 12 doses (6 weeks) OR 5 days/week for 10 doses (2 weeks)[c] then twice	2a 2b[e]	INF/RIF INH/RPT	Twice weekly for 36 doses (18 weeks) Once weekly for 18 doses (18 weeks)	62–58 (26 weeks) 44–40 (26 weeks)	A (II) B (I)	B (II)[d] E (I)

		weekly for 12 doses (6 weeks)						
3	INH RIF PZA EMB	3 times weekly for 24 doses (8 weeks)	3a	INH/RIF	3 times weekly for 54 doses (18 weeks)	78 (26 weeks)	B (I)	B (II)
4	INH RIF EMB	7 days/week for 56 doses (8 weeks) Or 5 days/week for 40 doses (8 weeks)[c]	4a	INH/RIF	7 days/week for 217 doses (31 weeks) Or 5 days/week for 155 doses (31 weeks)[c]	273–195 (39 weeks)	C (I)	C (II)
			4b	INH/RIF	Twice weekly for 62 doses (31 weeks)	118–102 (39 weeks)	C (I)	C (II)

[a] Definitions of evidence ratings: A, preferred; B, acceptable alternative; C, offer when A and B cannot be given; E, should never be given; I, randomized clinical trial; II, data from clinical trials that were not randomized or were conducted in other populations; III, expert opinion.

[b] Patients with cavitation on initial chest radiograph and positive cultures at completion of 2 months of therapy should receive a 7-month continuation phase (31 weeks; either 217 doses [daily] or 62 doses [twice weekly]).

[c] Five-day-a-week administration is always given by directly observed therapy (DOT). Rating for 5 days/week regimens is A (III).

[d] Not recommended for HIV-infected patients with CD4+ cell counts <100 cells/μL.

[e] Options 1c and 2b should be used only in HIV-negative patients who have negative sputum smears at the time of completion of 2 months of therapy and who do not have cavitation on the initial chest radiograph.

EMB, ethambutol; INH, isoniazid; PZA, pyrazinamide; RIF, rifampin; RPT, rifapentine.

Table 68-3

Drugs Used in the Treatment of Tuberculosis in Adults and Children (continued)

Drug	Dosing (Maximum Dose)	Primary Side Effects	Dose Adjustment in Renal Impairment	Comments
First-Line Agents				
Isoniazid	Adults: 5 mg/kg (300 mg) daily; 15 mg/kg (900 mg) once, twice, or	Increased aminotransferases (asymptomatic), clinical	No	Peripheral neuropathy preventable with

	thrice weekly Children: 10–15 mg/kg (300 mg) daily; 20–30 mg/kg (900 mg) twice weekly	hepatitis, peripheral neuropathy, CNS effects, lupus-like syndrome, hypersensitivity reactions		pyridoxine 10–25 mg. Hepatitis more common in older patients and alcoholics. Potent inhibitor of CYP2C9, CYP2C19, CYP2E1. ↑ serum level of phenytoin
Rifampin	Adults: 10 mg/kg (600 mg) once daily, twice weekly, or thrice weekly Children: 10–20 mg/kg (600 mg) once daily or twice weekly	Pruritus, rash, hepatotoxicity, GI (nausea, anorexia, abdominal pain), flu-like syndrome, thrombocytopenia, renal failure	No	Orange-red discoloration of body secretions (sweat, saliva, tears, urine). Potent inducer of CYP3A4, CYP1A2, CYP2A6, CYP2B6, CYP2C8, CYP2C9, CYP2C19, and CYP3A5.
Rifabutin	Adults: 5 mg/kg (300 mg) once daily, twice weekly, or thrice weekly Children: unknown	Neutropenia, uveitis, GI symptoms, polyarthralgias, hepatotoxicity, rash	No	Orange-red discoloration of body secretions (sweat, saliva, tears, urine). Weaker inducer of hepatic microsomal enzymes than rifampin.
Rifapentine	Adults: Active disease, 10 mg/kg (600 mg) once weekly during continuation phase; latent infection, 15 mg/kg (900 mg) once weekly Children 2-11 years: 15 mg/kg (900 mg) once weekly	Similar to rifampin	Unknown	Drug interactions due to induction of hepatic microsomal enzymes (see rifampin).
Pyrazinamide	Adults: 40–55 kg: 1 g daily, 2 g twice weekly, 1.5 g thrice weekly; 56–75 kg: 1.5 g daily, 3 g twice weekly, 2.5 g thrice weekly; 76–90 kg: 2 g daily, 4 g twice weekly, 3 g thrice weekly Children: 15–30 mg/kg (2 g) daily; 50 mg/kg (2 g) twice weekly	Hepatotoxicity, nausea, anorexia, polyarthralgias, rash, hyperuricemia, dermatitis	Yes	Monitor aminotransferases monthly.
Ethambutol	Adults: 40–55 kg: 800 mg daily, 2 g twice weekly, 1.2 g thrice weekly; 56–75 kg: 1.2 g	Optic neuritis, skin rash, drug fever	Yes	Routine vision tests recommended; 50% excreted unchanged in urine.

	daily, 2.8 g twice weekly, 2 g thrice weekly; 76–90 kg:1.6 g daily, 4 g twice weekly, 2.4 g thrice weekly Children: 15–20 mg/kg (1 g) daily; 50 mg/kg (2.5 g) twice weekly			

Second-Line Agents				
Cycloserine	Adults: 10–15 mg/kg/day (1 g), usually 500–750 mg/day in 2 divided doses Children: 10–15 mg/kg/day (1 g)	CNS toxicity (psychosis, seizures), headache, tremor, fever, skin rashes	Yes	May exacerbate seizure disorders or mental illness. Some toxicity preventable by pyridoxine (100–200 mg/day). Monitor serum concentrations (peak 20–35 mcg/mL desirable).
Ethionamide	Adults: 15–20 mg/kg/day (1 g), usually 500–750 mg/day in one daily dose or 2 divided doses Children: 15–20 mg/kg/day (1 g)	GI effects (metallic taste, nausea, vomiting, anorexia, abdominal pain), hepatotoxicity, neurotoxicity, endocrine effects (alopecia, gynecomastia, impotence, hypothyroidism), difficulty in diabetes management	Yes	Must be given with meals and antacids. Monitor aminotransferases and thyroid-stimulating hormone monthly.
Streptomycin	Adults: 15 mg/kg/day (1 g); ≥60 years, 10 mg/kg/day (750 mg) Children: 20–40 mg/kg/day (1 g)	Vestibular or auditory dysfunction of eighth cranial nerve, renal dysfunction, skin rashes, neuromuscular blockade	Yes	Audiometric and neurologic examinations recommended; 60%–80% excreted unchanged in urine. Monitor renal function.
Amikacin	Adults: 15 mg/kg/day (1 g); ≥60 years, 10 mg/kg/day (750 mg) Children: 15–30 mg/kg/day (1 g)	Ototoxicity, nephrotoxicity	Yes	Less vestibular toxicity than streptomycin. Monitoring similar to streptomycin.
Capreomycin	Adults: 15 mg/kg/day (1 g); ≥60 years, 10 mg/kg/day (750 mg) Children: 15–30	Nephrotoxicity, ototoxicity	Yes	Monitoring similar to streptomycin.

	mg/kg/day (1 g) as single dose or twice-weekly dose			
p-Aminosalicylic acid (PAS)	Adults: 8–12 g/day in 2–3 doses Children: 200–300 mg/kg/day in 2–4 divided doses	GI intolerance, hepatotoxicity, malabsorption syndrome, hypothyroidism	Yes	Liver enzymes and thyroid function should be monitored.
Levofloxacin	Adults: 500 to 1,000 mg/day	Nausea, diarrhea, abdominal pain, anorexia, headache, dizziness, QT prolongation, tendon pain or rupture	Yes	Do not give with divalent or trivalent cations (aluminum, magnesium, iron, etc.).
Moxifloxacin	Adults: 400 mg/day	Nausea, diarrhea, abdominal pain, anorexia, headache, dizziness, QT prolongation, tendon pain, or rupture	No	See levofloxacin.
Bedaquiline	Adults: 400 mg once daily for 2 weeks, then 200 mg thrice weekly for 22 weeks	Nausea, arthralgias, headache, increased transaminases, hemoptysis, chest pain, anorexia, rash, QT prolongation	No	Take with food. CYP3A4 substrate, avoid concomitant administration with inducers and inhibitors. Increased mortality compared to placebo.

CNS, central nervous system; GI, gastrointestinal.

Fixed-dose combinations of drugs have been advocated to improve adherence to the prescribed regimen, especially during the critical initial treatment phase. There are two fixed-dose combination preparations available in the United States: Rifamate, which contains isoniazid 150 mg and rifampin 300 mg/capsule, and Rifater, which contains isoniazid 50 mg, rifampin 120 mg, and pyrazinamide 300 mg/tablet. These formulations are a means of minimizing inadvertent monotherapy, especially when DOT is not possible, and they may decrease the risk of acquired drug resistance while reducing the number of capsules or tablets that must be ingested each day.[33] Safety and efficacy of a four-drug fixed-dose combination regimen was compared with each drug administered separately in patients with pulmonary TB.[67] The combination tablet contained isoniazid 75 mg, rifampin 150 mg, pyrazinamide 400 mg, and ethambutol 275 mg, and two to five tablets were ingested per day based on body weight. The number of patients who were culture negative at 18 and 24 months was similar between the treatment groups, in addition to the number of treatment failures, relapses, and death. The four-drug fixed-dose combination was noninferior to each drug administered separately.[67] It should be noted that there was no difference in outcomes based on HIV status, but less than 7% of the study subjects were HIV positive.[67]

The high risk of transmission of M. tuberculosis to other persons mandates that hospitalized persons with suspected or confirmed infectious TB be placed in respiratory isolation until they are determined not to have TB, they are discharged from the hospital, or they are confirmed to be noninfectious.[34] Based on H.G.'s subjective and objective findings, he should be placed in respiratory isolation. H.G.'s symptoms should improve within the first 4 weeks. He would be considered to be noninfectious when he is receiving effective drug therapy, is improving clinically, and has had negative results for three consecutive sputum AFB smears collected on different days.[34] Patients who have responded clinically may be discharged to home despite positive smears if their household contacts have already been exposed and these contacts are not at increased risk of TB (e.g., infants, HIV-positive and immunosuppressed persons). In addition, patients discharged to home with positive smears must agree not to have contact with other susceptible persons.[34]

Fluoroquinolones as Initial Therapy

Interest in fluoroquinolones for the treatment of TB dates back more than 30 years with a report describing the use of ofloxacin in 19 patients with chronic, drug-resistant TB disease.[68] Several fluoroquinolones possess in vitro activity against M. tuberculosis, but moxifloxacin and gatifloxacin are four- to eightfold more potent than levofloxacin.[69] Moxifloxacin was compared with ethambutol in the first 2 months of treatment in adults with smear-positive pulmonary TB.[70] Patients were randomly assigned to receive moxifloxacin 400 mg daily or ethambutol (based on body weight), and all patients received isoniazid, rifampin, and pyrazinamide. Patients receiving moxifloxacin were more likely to have negative sputum cultures at 4 weeks and 6 weeks, but the 2-month conversion rates were equal in each group.[70] In another study, sputum culture conversion at 8 weeks was significantly greater in patients treated with moxifloxacin when compared with ethambutol (80% vs. 63%).[71] Culture conversion rates were also significantly higher in the moxifloxacin group at weeks 1, 2, 3, and 4, and the median time to consistently negative cultures was 35.0 days in the moxifloxacin group and 48.5 days in the ethambutol group.[71]

Moxifloxacin has been compared with isoniazid during the intensive phase of treatment of pulmonary TB.[72] Patients were randomly assigned to receive moxifloxacin 400 mg or isoniazid 300 mg daily, and all patients received rifampin, pyrazinamide, and ethambutol.[72] After 8 weeks, negative sputum cultures were observed in 60.4% of the patients in the moxifloxacin group and 54.9% of patients in the isoniazid group, but this difference was not statistically significant.[72]

Despite the reported efficacy of fluoroquinolones in the treatment of TB, clinicians must be cognizant of the potential development of resistance to this important drug class. Fluoroquinolone resistance in M. tuberculosis has been described, occurring more frequently in multidrug-resistant isolates.[73] Fluoroquinolones are the most commonly prescribed antibiotic class in the United States, and outpatient use for infections other than TB could be a potential risk factor for TB resistance in a patient who becomes infected with M. tuberculosis. In a study evaluating risk factors for fluoroquinolone-resistant M. tuberculosis, investigators identified newly diagnosed patients with culture-confirmed TB in a Medicaid population.[74] Of the 640 patients evaluated, 116 (18%) patients had fluoroquinolone exposure within the 12 months before diagnosis with TB, and 16 (2.5%) patients were infected with M. tuberculosis strains that were fluoroquinolone resistant.[74] The study found that receipt of a fluoroquinolone for more than 10 days, occurring more than 60 days before diagnosis of TB, was associated with the highest risk for fluoroquinolone resistance.[74] Therefore, judicious use of fluoroquinolones, especially in patients at risk for TB infection, is mandatory to maintain the utility of fluoroquinolones in the treatment of TB.

Susceptibility Testing

Drug susceptibility testing is essential to ensure proper treatment of patients with active disease and should be performed on the initial isolate of M. tuberculosis from all patients.[18] Susceptibility testing should also be performed if cultures remain positive after 3 months of therapy or if negative cultures become positive after a period of time. Traditionally, susceptibility testing is performed by growing the organism on solid or in liquid media containing the drug. The agar proportion method allows for quantitation of the proportion of organisms that are resistant to a given drug, which is expressed as a percentage of the total organism population tested.[18] A drug will not be useful for therapy if 1% or more of the total population are resistant to the drug. Unfortunately, susceptibility results may not be available for several weeks because of the slow growth of the organism and the need to isolate the pathogen before susceptibility testing can be performed.[18]

To expedite susceptibility reporting, molecular drug resistance tests have been developed to detect mutations in the chromosomal sequence encoding for resistance to a specific drug directly on clinical specimens without the need for growth on culture.[54],[55] For example, mutations in the rpoB gene block the activity of rifampin by preventing the drug from binding to RNA polymerase. Approximately 95% of rifampin-resistant M. tuberculosis carry this mutation, and treatment failures have been associated with the presence of rpoB mutations.[75],[76] The molecular drug resistance test amplifies the target genetic sequence using polymerase chain reaction, and a second assay, such as DNA sequencing and hybridization assays, is used to determine whether the sequence contains a mutation associated with drug resistance. If a mutation is detected, the organism is considered to be drug resistant, but the organism is presumed to be drug susceptible if a mutation is not detected. Molecular tests can reliably detect the presence of known mutations within 1 to 2 days, which may result in earlier initiation of effective therapy, shorter durations of infectivity, and reduced spread of TB. However, these molecular drug resistance tests can only detect a specific set of known mutations and cannot identify novel mutations conferring resistance.[55] Therefore, traditional susceptibility testing continues to play an important role in confirming results of molecular testing.[54]

Kits for detecting mutations associated with rifampin resistance include GenoType MTBDR(plus) and INNO-LiPA Rif.TB. Compared with culture-based drug resistance tests, the sensitivity and specificity of the MTBDR(plus) line-probe assay were 98% and 99%, respectively, for detecting rifampin resistance in isolates or directly from clinical specimens.[77],[78] The sensitivity of the INNO-LiPA Rif.TB assay ranged from 80% to 100% and the specificity was 100% for detecting rifampin resistance directly from clinical specimens.[77],[78] Molecular beacons are hybridization probes that use fluorescent-labeled, hairpin-shaped DNA probes with a fluorophore adjacent to a molecule that prevents fluorescence.[35] Using a real-time polymerase chain reaction assay, fluorescence occurs if the amplified PCR products have the wild-type gene sequence, but fluorescence is not detected if mutations are present in the target sequence. These tests have high sensitivity (96%–97%) and specificity (99%–100%) for rifampin resistance in clinical specimens.[79] Molecular drug resistance tests for other antitubercular drugs are not fully developed compared with tests for rifampin resistance. For detecting mutations associated with isoniazid resistance, the specificity of the MTBDR(plus) assay was 100%, but the sensitivity ranged from 57% to 100% (pooled sensitivity 85%).[79] However, rifampin resistance is a reliable surrogate for MDR-TB in the United States because isolated rifampin resistance is uncommon.

The Xpert MTB/RIF assay is an automated molecular-based test that uses nested real-time polymerase chain reaction, allowing for simultaneous detection of M. tuberculosis and rifampin resistance. The test is approved for diagnostic testing of raw sputum samples, and results are available within 2 hours.[54] Sensitivity is 95% to 98.2% in AFB culture or smear-positive specimens, but performance is correlated with bacterial load because sensitivity is only 55% to 72.5% in smear-negative specimens.[80],[81] Sensitivity is also lower in patients with HIV infection. Specificity was 94% to 99.2% in patients with negative cultures.[80],[81] The Xpert MTB/RIF test also correctly identified 98.1% of patients with rifampin-susceptible bacilli and 97.6% of patients with rifampin-resistant bacilli.[80]

CASE 68-1, QUESTION 9: Is H.G. a risk to the community and does anyone need to know?

Yes! Each case of active TB disease must be reported to the local, state, or both public health departments.[18],[34],[82] This not only results in optimal therapy by monitoring adherence to therapy, but it also ensures that contact and source-case investigations will be performed. All individuals who have been in close contact to H.G. should be evaluated for latent TB infection or active disease. Considering their close contact to H.G. and his coworkers, his family members should be evaluated. Reporting of cases also permits record-keeping and surveillance to determine whether public health TB control efforts are achieving their goal of preventing the spread of TB.[34],[82]

Continuation Therapy

REGIMENS

CASE 68-1, QUESTION 10: Four weeks later, H.G.'s initial sputum cultures were reported to be positive for M. tuberculosis. Drug susceptibility testing to isoniazid and rifampin revealed susceptibility to both agents. What drug regimen should be used for continued treatment of H.G.? How long should treatment be continued?

Successful treatment of uncomplicated TB can be achieved in 6 months (26 weeks) if isoniazid, rifampin, pyrazinamide, and ethambutol are used for the first 2 months (8 weeks) and if patient adherence to the regimen and the organism susceptibility can be assured.[33] Therefore, after 8 weeks of DOT with isoniazid, rifampin, pyrazinamide, and ethambutol, H.G.'s regimen may be streamlined to isoniazid and rifampin daily (5 days or 7 days/week) or 2 to 3 times/week under continued DOT for an additional 18 weeks (Table 68-2). Because H.G. is HIV negative and cavitary lesions were not present on his chest radiograph, he may also be a candidate for once-weekly administration of isoniazid and rifapentine, as long as his sputum AFB smear is negative after completing the initial 8 weeks of therapy.[33]

The effectiveness of a primarily twice-weekly treatment regimen has been demonstrated in both pulmonary and extrapulmonary TB.[83] The regimen consisted of isoniazid 300 mg, rifampin 600 mg, pyrazinamide 1.5 to 2.5 g, and streptomycin 750 to 1,000 mg intramuscularly daily for 2 weeks, followed by the same drugs twice weekly for an additional 6 weeks. The regimen was then reduced to isoniazid and rifampin twice weekly for the remaining 16 weeks (4 months). At 3 months, 75% of patients had negative sputum cultures, and all patients were culture negative at 20 weeks.[83] Relapse occurred in two patients and only minor adverse effects were reported. Another important feature is that this regimen is highly cost-effective. Among the 6- and 9-month regimens, it is the second lowest in cost, primarily because of the least number of patient–healthcare worker encounters (62 directly observed doses).

If pyrazinamide cannot be included in the initial regimen, therapy should be initiated with isoniazid, rifampin, and ethambutol for the first 8 weeks. Therapy should be continued with isoniazid and rifampin for 31 weeks given either daily or twice weekly.[33] If drugs other than isoniazid and rifampin are used in the initial phase, treatment must be continued for 18 to 24 months.[66]

Twice-weekly administration of isoniazid (900 mg) and rifampin (600 mg) is recommended for H.G. because this approach requires fewer doses and should result in substantial cost savings.[33] In addition, the relapse rates for the twice- and thrice-weekly isoniazid and rifampin continuation regimens are significantly lower than the once-weekly regimen of isoniazid and rifapentine 600 mg.[84],[85] Five characteristics were associated with increased relapse risk in the isoniazid and rifapentine group: sputum culture positive at 2 months; cavitation on chest radiograph; underweight; bilateral pulmonary involvement; non-Hispanic Caucasian race.[85] A potential explanation for these results is the high protein binding of rifapentine (98%). A study evaluated the safety and tolerability of rifapentine 600, 900, and 1,200 mg once weekly (with isoniazid 15 mg/kg) in 150 HIV-negative patients.[86] A trend toward more adverse events was observed in the 1,200-mg treatment arm ($p = 0.051$), but the 900-mg dose was well tolerated.[86] However, relapse rates for the higher-dose weekly rifapentine regimens with isoniazid are unknown. A subsequent study demonstrated that low plasma concentrations of isoniazid were associated with failure or relapse with once-weekly isoniazid and rifapentine.[87] Two patients who relapsed with M. tuberculosis monoresistant to rifamycin had very low isoniazid concentrations. Rapid acetylation status was a risk factor in those patients who failed or relapsed.[87] Rifamycin pharmacokinetics did not influence patient outcomes, however.[87]

Treatment with isoniazid and rifampin should be continued for a minimum total duration of 26 weeks. A full course of therapy can be more accurately determined by the total number of doses ingested, not solely by the duration of therapy.[33] Thus, 26 weeks is the minimum duration of treatment and accurately indicates the amount of time the drugs are given only if there are no interruptions in drug administration.[33] Pyridoxine 10 to 25 mg/day should be continued throughout the treatment period. If H.G. is symptomatic, or smear or culture is positive after 3 months of therapy, he should be re-evaluated for possible nonadherence with his therapy, malabsorption of the drugs, or infection with drug-resistant organisms. Evaluation should include a second culture and a second susceptibility test, consideration of DOT (if not already instituted), and consultation with experts in the treatment of TB.[34]

CASE 68-1, QUESTION 11: H.G. is concerned about the long duration required for treatment of his infection. He asks whether there is any way to shorten the length of treatment. Are there any effective treatment regimens that may be administered for less than 26 weeks?

Treatment of active TB for 26 weeks is a challenge to ensure patients adhere to the prescribed regimen for the total duration of therapy. Shorter-course treatment regimens, if efficacious, could be helpful in improving adherence rates, decreasing treatment costs, and reducing adverse events. Three published studies evaluated the treatment of drug-susceptible TB for a total duration of 4 months using modified regimens that included a fluoroquinolone (moxifloxacin or gatifloxacin).[88–90] The control regimen was the same in each study and consisted of 8 weeks of isoniazid, rifampin, pyrazinamide, and ethambutol followed by isoniazid and rifampin for 18 weeks. In all three studies, unfavorable outcomes and culture-confirmed relapse/recurrence were more common in patients receiving the short-course regimens; therefore, noninferiority was not demonstrated for any of the 4-month regimens.[88–90] Based on these studies, H.G. should receive 26 weeks of therapy, and every effort should be made to ensure adherence to the treatment regimen.

Directly Observed Therapy

CASE 68-1, QUESTION 12: What is directly observed therapy, and why is it important for H.G. to be treated by directly observed therapy?

Directly observed therapy (DOT) is the practice of a healthcare provider or other responsible person observing as the patient ingests and swallows the TB medications. DOT is the preferred core management strategy for all patients with TB.[33–35] The purpose of DOT is to ensure adherence to TB therapy. DOT not only ensures completion of therapy, but it may also reduce the risk of developing drug resistance. By improving these two factors, it also reduces the risk of transmission of TB to the community. DOT can be administered with daily or twice- and thrice-weekly regimens. It can be administered to patients in the office or clinic setting, or it can be given at the patient's home, school, or work.[33,66] Often, enablers or incentives, such as food, clothing, or transportation, are used to improve adherence to DOT. A comprehensive review of DOT-related articles found that the completion rate of TB therapy exceeds 90% when DOT is used along with enablers.[35,91] A study found that culture-positive patients treated for active pulmonary TB with DOT had significantly higher cure rates (97.8% vs. 88.6%; $p < 0.002$) and lower TB-related mortality (0% vs. 5.5%; $p = 0.002$) compared with patients treated using self-administered therapy.[92] Although DOT is recommended for all patients, public health departments may not be able to provide DOT for all patients because of the associated costs. The initial cost of DOT is greater than self-administered therapy; however, when costs of relapse and failure are included in a cost-effectiveness analysis, DOT is significantly less expensive than self-administered therapy.[93] When drug resistance develops (in those instances in which DOT is not used), the cost of salvage therapy increases to $180,000.00 per patient.[94] It is, therefore, widely accepted that patients with TB should receive DOT.[93],[95]

Multiple-Drug Therapy

CASE 68-1, QUESTION 13: Why are multiple drugs recommended for treatment of active TB disease? What is the role of each drug in the treatment of active TB?

The key to treating active TB disease is multiple-drug therapy for a period sufficient to kill the organisms and to prevent development of resistant strains of M. tuberculosis. Most cavitary lesions contain a concentration of 10^9 to 10^{12} organisms, and the frequency of mutations that confer resistance to a single drug is approximately 10^{-6} for isoniazid and streptomycin, 10^{-8} for rifampin, and 10^{-5} for ethambutol.[33] Considering the inoculum of organisms involved, patients with active TB disease likely harbor organisms with random mutations that confer drug resistance to a given drug. If a single drug is given, it would reduce the number of drug-susceptible organisms but allow the drug-resistant organisms to replicate. By using multiple-drug therapy, the likelihood of encountering organisms with mutations to multiple drugs is reduced. For example, the frequency of concurrent mutations to isoniazid and rifampin would be 10^{-14} (10^{-6} for isoniazid and 10^{-8} for rifampin), making simultaneous resistance to both drugs an unlikely event in an untreated patient.[33] Therefore, monotherapy should never be used in the treatment of active TB disease.[33],[94]

Multiple-drug therapy also serves to sterilize the sputum and lesions as quickly as possible. The drugs available for the treatment of TB vary in their ability to accomplish this task.[33] Drugs effective against tubercle bacilli can be divided into first-line and second-line agents (Table 68-3). The foundation of treatment should be with first-line agents, such as isoniazid, rifampin, pyrazinamide, and ethambutol. Of the various agents, isoniazid has the most bactericidal activity versus rapidly multiplying M. tuberculosis during the initial phase of therapy (early bactericidal activity), followed by ethambutol, rifampin, and streptomycin.[96–98] Drugs that have potent early bactericidal activity more rapidly decrease the infectiousness of the patient and reduce the likelihood of developing resistance.[33] Pyrazinamide has weak early bactericidal activity during the first 2 weeks of therapy and is less effective at preventing emergence of drug resistance than isoniazid, rifampin, and ethambutol.[33],[96],[99] Therefore, pyrazinamide should not be combined with only one other agent when treating active TB disease. Rifampin also has activity against intracellular organisms that are usually dormant but undergo periods of active growth. This ability to penetrate and destroy the persistent intracellular organisms makes rifampin extremely valuable in short-course chemotherapy regimens.[100]

Pyrazinamide is most effective against tubercle bacilli in the acidic environment within the macrophage or areas of tissue necrosis. In addition, it is most effective in sterilizing lesions when used in the first 2 months of treatment, but it does not offer substantial sterilizing activity after 2 months. Pyrazinamide should be considered an essential component of short-course regimens.[33],[66]

Ethambutol is bacteriostatic at low doses, but bactericidal at higher doses. It is moderately effective against the fast-growing bacilli. It has little sterilizing activity and is primarily used to prevent the emergence of drug-resistant organisms.[66]

Streptomycin is bactericidal against rapidly multiplying extracellular organisms and is effective when given daily for 2 months followed by twice- or thrice-weekly administration thereafter. In the past, streptomycin was administered by intramuscular injection, but these intramuscular injections were painful. Therefore, although it is not labeled for intravenous use, streptomycin may be given in 50 to 100 mL of 5% dextrose in water or normal saline and infused for 30 to 60 minutes.[101] Streptomycin can cause ototoxicity and nephrotoxicity, as with other aminoglycosides.

Other drugs used in the treatment of TB (bedaquiline, capreomycin, amikacin, cycloserine, ethionamide, p-aminosalicylic acid) are usually reserved for cases involving drug-resistant organisms, treatment failures, drug toxicity, or patient intolerance to the other agents. Their use is discussed later in the chapter.

Monitoring Drug Therapy

CASE 68-1, QUESTION 14: What subjective and objective findings should be followed to ensure therapeutic efficacy and to minimize drug toxicity? Should H.G. be followed closely after completion of his treatment regimen?

H.G. should be questioned about the occurrence of adverse reactions associated with his therapy (Table 68-3). Specifically, he should be asked about anorexia, nausea, vomiting, or abdominal pain, which may be an indication of possible hepatitis secondary to isoniazid, rifampin, or pyrazinamide. He should be questioned about numbness and tingling in his extremities; however, isoniazid-induced peripheral neuropathy should not be a problem in H.G. because he is also taking pyridoxine, which should prevent this adverse effect. H.G. also should be examined for, and

---

questioned about, petechiae or bruises, because thrombocytopenia occurs occasionally with intermittent rifampin therapy. This effect purportedly occurs more frequently with intermittent rifampin therapy, but it is rare at the currently recommended intermittent rifampin dose of 10 mg/kg/day (≈600 mg).[66]

In a study comparing 6- versus 9-month antituberculosis therapies of mostly isoniazid and rifampin, the incidence of side effects was similar between the two groups. Adverse effects occurred in 7.7% of patients in the 6-month arm compared with 6.4% in the 9-month arm, a difference that was not statistically significant.[102] Hepatic abnormalities occurred in 1.6% of patients in the 6-month regimen, a nonsignificant difference from patients in the 9-month regimens (1.2%). Hematologic events were rare at 0.2% and 0.0% in the 6- and 9-month groups, respectively. Other reported effects, gastrointestinal (GI) problems, rash, and arthralgias were minor and infrequent in both regimens.[102]

OBJECTIVE SIGNS

A pretreatment complete blood count, platelet count, blood urea nitrogen, hepatic enzymes (serum aminotransferases), bilirubin, and serum uric acid should be evaluated. Baseline visual examination should also be considered for patients receiving ethambutol. These tests are performed to detect any abnormality that may complicate or necessitate modification of the prescribed regimen. These tests should be repeated if the patient experiences any evidence of drug toxicity or has abnormalities at baseline.[33],[66]

H.G. is 35 years of age and at increased risk for development of drug-induced hepatotoxicity. Isoniazid can cause asymptomatic increases in serum transaminases as well as overt hepatitis.[33] Pyrazinamide has also been associated with hepatotoxicity, but the incidence is less common at doses of 25 mg/kg/day or less. Transient asymptomatic hyperbilirubinemia and cholestatic hepatitis can occur in patients receiving rifampin.[33] Therefore, it is important that H.G. be educated about possible symptoms of hepatotoxicity, primarily nausea, vomiting, abdominal pain, anorexia, and jaundice. Monthly serum liver function tests (LFTs) are no longer recommended because they are costly, and transient, asymptomatic elevations in LFTs may occur, which could result in unnecessary discontinuation of optimal therapy. The CDC recommends that medical personnel question patients about symptoms once monthly.[66]

Sputum cultures and smears for AFB should be ordered every 2 to 4 weeks initially and then monthly after the sputum cultures become negative. With appropriate therapy, sputum cultures should become negative in more than 85% of patients after 2 months. Radiologic examination (chest radiographs) is not as important as sputum examination, but it may be useful at the completion of therapy to serve as a comparison for any future films.

Patients who are culture positive at 2 months need to be carefully re-examined. Drug susceptibility testing should be performed to rule out acquired drug resistance, and special attention should be given to drug adherence (i.e., DOT should be used). If drug resistance is demonstrated, the regimen should be modified as needed. Sputum cultures should also be obtained monthly until negativity is achieved.[66]

As was the case for H.G., weight loss and nutritional depletion are common in patients with active TB disease. In a large TB treatment study, 7.1% of patients experienced relapse, with relapse greatest in patients who were underweight at diagnosis or with a body mass index less than 18.5 kg/m^2.[103] In those patients underweight at diagnosis (defined as ≥10% below ideal body weight), weight gain of 5% or less between diagnosis and completion of 2 months of therapy was independently associated with relapse.[103] In addition, the relapse rate was 50.5% in underweight patients with a cavitary lesion on chest radiograph, positive sputum cultures after 2 months of therapy, and a 5% or less weight gain in the first 2 months of therapy.[103] Therefore, it may be prudent to monitor H.G.'s body weight during the initial 2 months of therapy, and he may need to receive more intensive therapy or a longer duration of therapy.

Routine follow-up usually is not required after the successful completion of chemotherapy with isoniazid and rifampin. It may be prudent, however, to re-examine the patient 6 months after completion of therapy or at the first sign of any symptoms suggestive of active TB. This is especially important in patients who were slow to respond to therapy or who have significant radiologic findings at completion of therapy. These recommendations are only for those patients with organisms fully susceptible to the medications being used.[66]

Patients who are culture negative but have radiographic abnormalities consistent with TB should have an induced sputum or bronchoscopy performed to establish a microbiologic diagnosis and monitored radiographically. Patients with extrapulmonary TB should be evaluated according to the site of involvement.[33],[66]

Treatment Failure

CASE 68-1, QUESTION 15: If H.G. does not respond to his currently prescribed treatment regimen, should one more drug be added to his regimen?

No! Adding a single drug to a failing regimen is the most common and devastating prescribing error in TB therapy. This practice is essentially monotherapy because the assumption is that the organisms are resistant to the medications currently being used. Resistance to the new drug will eventually develop, further reducing the patient's chance of cure. At least two, and preferably three, new drugs to which susceptibility can be inferred should be added to lessen the probability of further acquired drug resistance. Empiric retreatment regimens may include a fluoroquinolone, bedaquiline, an injectable agent (e.g., streptomycin, amikacin, or capreomycin), and an additional oral agent (e.g., p-aminosalicylic acid, cycloserine, or ethionamide).[33] New drug susceptibility testing should be performed and treatment adjusted accordingly.[33],[94]

TREATMENT OF LATENT TUBERCULOSIS

CASE 68-2

QUESTION 1: J.G., the 32-year-old wife of H.G., and their children are tested to determine whether they have been infected with M. tuberculosis. For his wife, the induration from 5 TU of PPD was 12 mm, which is reported as positive. J.G. states that she has never received the BCG vaccine. The PPD results for the children were negative. J.G. does not have any clinical symptoms or radiographic findings suggestive of active TB at this time, and her current weight is 60 kg. Is she at risk of developing active disease? What are the current recommendations for drug therapy for persons with latent TB infection? Should J.G. receive treatment?

Because J.G. is a household contact of a person with active TB disease and has a positive tuberculin skin test, she is at great risk of developing active disease.[22],[23],[48],[49] During the first year after infection from the index case, a household contact's risk of developing active disease is 2% to 4%, and contacts with a positive tuberculin skin test are at the greatest risk.[66] As with active disease, the tuberculin skin test is usually performed to detect the presence of latent TB infection. However, for contact investigation, studies have demonstrated that IGRAs are a more accurate indicator of the presence of latent TB infection than tuberculin skin testing.[104],[105]

Therefore, many health departments in the United States have adopted IGRAs as screening tests for contact investigations.[106] The majority of people with a negative IGRA after exposure to a person with active TB disease do not have TB infection; however, the immune reaction to TB can take several weeks to develop so the IGRA should be repeated 8 to 12 weeks after the last exposure to rule out infection.[23],[106] Tuberculin skin testing is preferred for screening children younger than 5 years old.[23]

Treatment of latent TB infection is effective in preventing active TB disease in patients with a positive tuberculin skin test or IGRA result and in those at risk for reactivation of active TB; therefore, it is strongly recommended.[22],[23] Treatment decreases the population of tubercle bacilli and reduces future morbidity from TB in the groups at high risk for developing active disease. Because J.G. is infected with M. tuberculosis but does not currently have active TB disease, she should be treated for latent TB infection.

There are four approved regimens for the treatment of latent TB.[22],[23] Isoniazid monotherapy prevents active TB in 90% of patients who complete a 9-month regimen compared to 60% to 80% of patients who complete a 6-month regimen.[107] Therefore, isoniazid 300 mg daily or 900 mg twice weekly for 9 months is preferred. The twice-weekly regimen should be administered by DOT to ensure patient adherence.[19] A 6-month regimen is an acceptable alternative in patients who cannot complete 9 months of therapy.[22] The benefits of treating latent TB infection outweigh the risks of isoniazid-induced hepatitis because all persons infected with TB are at risk for developing active disease throughout their lifetime. All patients receiving isoniazid should receive pyridoxine 25 mg/day to minimize the risk of peripheral neuropathy.

Unfortunately, patient adherence to these isoniazid regimens is very poor. In a population of patients beginning isoniazid treatment for latent TB, only 64% of patients completed at least 6 months of therapy.[108] Younger age, Hispanic ethnicity, and non-US country of birth were associated with greater likelihood of completing therapy.[108] Lower completion rates were associated with homelessness, excess alcohol intake, and experiencing an adverse event.[108] In another study, 52.7% of patients receiving treatment for latent TB infection failed to complete the prescribed course of therapy.[109] More than 93% of these patients were receiving isoniazid. Risk factors for failing to complete therapy included receipt of a 9-month isoniazid regimen, residence in a congregate setting (nursing home, shelter, jail), injection drug use, and employment at a healthcare facility.[109] In addition, this study reported that employees at healthcare facilities were more likely to decline treatment for latent TB infection.[109]

Because of concerns for isoniazid toxicity and abysmal adherence rates, shorter rifampin-based regimens may be utilized. Daily isoniazid plus rifampin for 3 months and daily rifampin monotherapy for 4 months are acceptable alternatives to isoniazid therapy.[22],[23],[107] For the patients randomly assigned to receive daily rifampin for 4 months, 91% took 80% of the doses, and 86% took more than 90% of the doses at 20 weeks.[110] For the patients randomly assigned to receive daily isoniazid for 9 months, 76% took 80% of the doses, and only 62% took more than 90% of the doses at 43 weeks.[110] Discontinuation of therapy due to an adverse events was more common in the isoniazid group (14%) versus the rifampin group (3%).[110] Another study reported significantly fewer grade 3 to 4 adverse events and hepatitis and significantly higher treatment completion rates with 4 months of rifampin compared with 9 months of isoniazid.[111] Rifampin for 4 months is an effective, safe, and cost-effective strategy to consider when treating latent TB infection in selected populations of patients.[110–114]

An attractive alternative for the treatment of latent TB infection is the combination of isoniazid and rifapentine administered once weekly for 12 weeks.[22],[23] In one study, patients received either isoniazid 15 to 25 mg/kg (maximal dose 900 mg) plus rifapentine 900 mg (with adjustments for patients weighing less than 50 kg) once weekly for 12 weeks by DOT or isoniazid 5 mg/kg (maximal dose 300 mg) once daily for 9 months.[115] Completion of therapy was significantly higher in the isoniazid/rifapentine group (82% vs. 69%; $p < 0.001$). Overall, TB developed in 7 of 3986 patients receiving isoniazid/rifapentine and 15 of 3,745 patients receiving isoniazid (hazard ratio 0.38 for the combination; 95% CI 0.15–0.99; $p = 0.05$).[115] Hepatotoxicity was higher in the isoniazid group (2.7% vs. 0.4%; $p < 0.001$), whereas hypersensitivity reactions were higher in the combination group (3.8% vs. 0.5%; $p < 0.001$). Permanent drug discontinuation for any reason was higher in the isoniazid group (31.0% vs. 17.9%; $p < 0.001$), but permanent drug discontinuation due to an adverse event was higher in the combination group (4.9% vs. 3.7%; $p = 0.009$).[115] The combination is recommended as an equal alternative to daily isoniazid for 9 months in patient 12 years or older with a greater risk of developing active TB disease.[116] These patients include those with recent exposure to a person with active TB, conversion of the tuberculin skin test or IGRA from negative to positive, or radiographic evidence of healed pulmonary TB. Isoniazid/rifapentine may also be considered in patients unlikely to complete 9 months of isoniazid or in a setting where the combination offers practical advantages (e.g., correctional facilities, homeless shelters). The combination is not recommended in women who are pregnant or who expect to become pregnant during treatment.

J.G. should be placed on isoniazid 300 mg/day or 900 mg twice weekly for at least 6 months and preferably up to 9 months, rifampin 600 mg for 4 months, or isoniazid 900 mg plus rifapentine 900 mg weekly for 12 weeks.[22],[23],[116] She should be educated and questioned frequently about the clinical symptoms of hepatitis, such as GI complaints. Pretreatment serum aminotransferases and bilirubin should be assessed to rule out preexisting liver disease. The American Thoracic Society and the CDC do not recommend routine monitoring of LFTs unless symptoms suggest hepatotoxicity.[66]

ADVERSE DRUG EVENTS

Isoniazid

HEPATOTOXICITY

CASE 68-2, QUESTION 2: J.G. is started on daily isoniazid. After 2 months of therapy, she presents to the clinic complaining of nausea, vomiting, and abdominal pain. Liver function tests were ordered, and her aspartate aminotransferase (AST) was 150 IU/L. Discuss the presentation, prognosis, and mechanism of isoniazid-induced hepatitis. What are the risk factors for developing hepatitis? Should isoniazid be discontinued to prevent further liver damage?

Approximately 10% to 20% of patients treated with isoniazid alone for latent TB infection will develop elevated serum aminotransferases, which are generally transient and asymptomatic.[33],[117] Most patients with mild, subclinical hepatic damage do not progress to overt hepatitis and recover completely even while continuing isoniazid. In contrast, continuation of isoniazid in patients with symptoms of hepatitis increases the risk of mortality compared with immediate discontinuation.[33] The risk of death from TB, however, is estimated to be 11 times higher than the risk of death from isoniazid hepatotoxicity.[118]

Isoniazid-induced hepatotoxicity generally occurs within weeks to months of initiating therapy; 60% of cases occur in the first 3 months and 80% occur in the first 6 months.[117] Constitutional symptoms may be seen early and may last from days to months. Nausea, vomiting, and abdominal pain are seen in 50% to 75% of patients with severe hepatotoxicity.[117] Jaundice, dark urine, and clay-colored stools may also be seen. Recovery may take weeks after discontinuing isoniazid therapy. The development of isoniazid hepatotoxicity has been linked to several factors, including acetylator phenotype, age, daily alcohol consumption, and concurrent rifampin use. Additionally, women may be at higher risk of death, especially during the postpartum period.[118]

The mechanisms responsible for isoniazid hepatotoxicity remain unclear. Previously, it was thought that rapid acetylators had a greater risk for isoniazid hepatotoxicity than slow acetylators. Rapid acetylators of isoniazid form monoacetylhydrazine, a compound that can cause liver damage, more rapidly than slow acetylators.[119] Rapid acetylators, however, would eliminate monoacetylhydrazine at a faster rate, and this should equalize the risk of toxicity between slow and fast acetylators.[120] One study demonstrated a different incidence of hepatitis between Asian men and women. Because both groups were fast acetylators, this study suggests that hepatitis is associated with factors other than acetylator phenotype.[121] Some evidence supports the theory that isoniazid-induced hepatitis is a hypersensitivity reaction; however, many patients tolerate isoniazid on rechallenge, discounting this theory.[122],[123]

Age and concurrent daily alcohol ingestion are the most consistent risk factors for isoniazid hepatitis.[66] Progressive liver damage is rare in persons younger than 20 years of age. It occurs in approximately 0.3% of persons between the ages of 20 and 34 years, 1.2% of those between the ages of 35 and 49 years, and 2.3% of persons older than 50 years of age.[66] One prospective cohort study, however, demonstrated a low incidence of isoniazid hepatitis. Of 11,141 patients receiving isoniazid alone for the treatment of latent TB infection, only 11 (0.1% of those starting and 0.15% of those completing therapy) developed clinical hepatitis.[124] Previous studies suggested a higher incidence of clinical hepatitis in patients receiving isoniazid alone, and a meta-analysis of six studies estimated the rate to be 0.6%.[33] However, severe hepatotoxicity may occur with isoniazid treatment of latent TB infection. The CDC reported 17 severe hepatic adverse events with isoniazid in 15 adults and 2 children (ages 11 and 14 years).[125] Five patients, including one child, underwent liver transplantation, and five adults died (including one liver transplant patient).

High-risk patients should be followed with routine monitoring of LFTs. These patients include those who consume alcohol daily, persons older than 35 years of age, those taking other hepatotoxic drugs, those with preexisting liver disease, intravenous drug users, black and Hispanic women, and all postpartum women. In these high-risk patients, isoniazid should be discontinued if the AST level exceeds 3 to 5 times the upper limit of the normal value.[66] Because J.G. is experiencing nausea, vomiting, and abdominal pain and her AST is greater than 3 times the upper range of the normal value, isoniazid should be discontinued temporarily until the AST returns to normal. At that time, isoniazid should be resumed, and her LFTs rechecked. If the AST increases again, the drug should be discontinued, and J.G. should be followed frequently for development of active TB.

CASE 68-3

QUESTION 1: C.M., an 80-kg, 35-year-old woman, is being treated for active TB disease with isoniazid 1,200 mg and rifampin 600 mg twice weekly. Is 1,200 mg of isoniazid twice weekly an appropriate dose for a 80-kg patient? What isoniazid side effects, other than hepatotoxicity, should be anticipated?

The usual twice-weekly isoniazid dose is 15 mg/kg, with a maximal dose of 900 mg. Even though she weighs 80 kg, C.M. should be receiving no more than 900 mg rather than 1,200 mg of isoniazid. Although high doses or increased serum concentrations have not been linked with hepatitis, elevated serum isoniazid concentrations have been associated with increased central nervous system (CNS) events, ranging from somnolence to psychosis and seizure. GI complaints are also more commonly observed at doses greater than 20 mg/kg.

PERIPHERAL NEUROPATHY

Although uncommon at the recommended daily and intermittent doses, isoniazid can cause a peripheral neuropathy by interfering with pyridoxine (vitamin B_6) metabolism.[33],[48] As many as 20% of patients may experience this problem with isoniazid doses greater than 6 mg/kg/day. Numbness or tingling in the feet or hands is the most common neuropathic symptom. In patients with medical conditions in which neuropathy is common, including diabetes mellitus, alcoholism, HIV infection, malnutrition, and renal failure, supplemental pyridoxine 25 mg/day should be given with isoniazid.[33],[48] Women who are pregnant or breast-feeding and persons with seizure disorders should also receive supplemental pyridoxine with isoniazid.[48]

ALLERGIC AND OTHER REACTIONS

Allergic reactions consisting of arthralgias, skin rash, swelling of the tongue, and fever have also been reported. Isoniazid has been associated with arthritic symptoms and systemic lupus erythematosus; approximately 20% of patients receiving isoniazid develop antinuclear antibodies.[33] Other less common reactions reported with isoniazid are dry mouth, epigastric distress, CNS stimulation and depression, psychoses, hemolytic anemia, pyridoxine-responsive anemia, and agranulocytosis.[122]

DRUG INTERACTIONS

Isoniazid is a relatively potent inhibitor of several cytochrome P450 isoenzymes (CYP2C9, CYP2C19, CYP2E1), but has minimal effects on CYP3A.[33] Isoniazid inhibits the hepatic metabolism of phenytoin and carbamazepine, resulting in increased plasma concentrations of these drugs. Patients receiving either of these two drugs with isoniazid should be observed for signs of phenytoin or carbamazepine toxicity, such as nystagmus, ataxia, headache, nausea, or drowsiness. Plasma phenytoin and carbamazepine concentrations should be monitored periodically so that the doses can be adjusted if necessary. Carbamazepine also may induce isoniazid hepatitis by inducing its metabolism to toxic metabolites.[126] In addition, isoniazid inhibits the metabolism of diazepam and triazolam. It is important to note that rifampin has the exact opposite effect on hepatic metabolism. Rifampin is a stronger inducer than isoniazid is an inhibitor as documented by the fact that isoniazid–rifampin combination therapy induces the metabolism of diazepam, phenytoin, and other agents metabolized by the cytochrome P450 system.[127]

Rifampin

FLU-LIKE SYNDROME

CASE 68-3, QUESTION 2: One month after beginning her twice-weekly DOT regimen, C.M. exhibited symptoms of myalgias, malaise, and anorexia. Laboratory data were normal except for a slightly decreased platelet count. Could C.M.'s symptoms be related to her drug therapy? What adverse reactions other than hepatotoxicity should be anticipated in a patient receiving rifampin?

A flu-like syndrome has been reported in 1% of patients receiving intermittent rifampin administration. This syndrome is rarely seen with usual doses of 600 mg twice weekly, but the incidence increases with twice-weekly doses greater than 900 mg. The incidence also increases if the dosing interval is increased to 1 week or longer.[128],[129] Unless the symptoms are severe, discontinuation of the drug is unnecessary. Because C.M. is receiving rifampin 900 mg twice weekly, her dose should be reduced to 600 mg and administered daily until the symptoms subside. Temporary administration of a nonsteroidal anti-inflammatory drug has been used to alleviate the flu-like symptoms. Twice-weekly therapy may then be resumed as long as the dose of rifampin dose does not exceed 600 mg.

p. 1436

---

p. 1437

HEPATOTOXICITY

Rifampin (rifapentine) is associated with a less than 1% rate of hepatotoxicity. Therefore, the risk of drug-induced hepatotoxicity is greater with isoniazid than with rifampin. On occasion, rifampin can cause hepatocellular injury and potentiate hepatotoxicity of other antituberculosis drugs.[117] Although elevations of liver enzymes may be seen, rifampin is more likely to produce cholestasis, as manifested by increases in alkaline phosphatase and hyperbilirubinemia without hepatocellular injury.[117] Elevations of all liver function tests may be seen transiently during the first month of rifampin therapy, but they are usually benign.[33]

THROMBOCYTOPENIA

Thrombocytopenia is more frequently associated with intermittent or interrupted rifampin administration, likely caused by production of immunoglobulin G and immunoglobulin M antibodies to rifampin. These antibodies likely fix complement onto platelets, resulting in platelet destruction. Hypothetically, intermittent or interrupted rifampin therapy results in increased antibody production. Once thrombocytopenia occurs with rifampin, its subsequent use is contraindicated because the problem will likely recur.[130],[131]

MISCELLANEOUS REACTIONS

In addition to the side effects associated with high-dose, intermittent therapy, 3% to 4% of patients taking normal doses of rifampin may experience adverse reactions.[130] The most common of these are nausea, vomiting, fever, and rash. Other reactions to rifampin include the hepatorenal syndrome hemolysis, leukopenia, anemia, and arthralgias as part of a suspected drug-induced lupus syndrome.[33],[132] Development of these latter reactions requires discontinuation of the drug.

ACUTE RENAL FAILURE

Acute renal failure has been reported rarely with rifampin.[33] This hypersensitivity reaction may occur with both intermittent and daily administration and may last as long as 12 months.[128] Rifampin should be discontinued, and other drugs (e.g., pyrazinamide and ethambutol) should be given. Doses of ethambutol and pyrazinamide should be adjusted for renal dysfunction, if necessary. Both rifampin and isoniazid may, however, be given in normal dosages to patients with preexisting renal failure.[133],[134]

DISCOLORATION OF BODY FLUIDS

Another important characteristic of rifampin relates to its chemical makeup. It is an orange-red crystalline powder that is distributed widely in body fluids. As a result, it can discolor saliva, tears, urine, sweat, and cerebrospinal fluid.[33] Patients using rifampin should be warned of this effect and cautioned not to use soft contact lenses because of possible discoloration. This effect may also be used to monitor adherence to rifampin therapy.

DRUG INTERACTIONS

Rifampin is a very potent inducer of cytochrome P450 CYP3A4 and also induces other cytochrome P450 isoenzymes, including CYP1A2, CYP2A6, CYP2B6, CYP2C8, CYP2C9, CYP2C19, and CYP3A5.[33],[135],[136] Rifampin induces phase 2 drug-metabolizing enzymes (e.g., UDP-glucuronyltransferases, sulfotransferases) and expression of transporter proteins (e.g., P-glycoprotein, multiple drug resistance protein 2, organic anion-transporting polypeptide).[135] Complete induction of these isoenzymes and transport proteins occurs approximately 1 week after starting rifampin and returns to baseline approximately 2 weeks after discontinuing the drug.[135] Rifamycins differ in their ability to induce cytochrome P450 isoenzymes, in which rifampin is the most potent, rifapentine is intermediate, and rifabutin is the least potent enzyme inducer.[33] Rifampin increases the metabolism of protease inhibitors, certain non-nucleoside reverse transcriptase inhibitors (NNRTIs), macrolide antibiotics, azole antifungal agents, corticosteroids, oral contraceptives, warfarin, cyclosporine, tacrolimus, theophylline, phenytoin, quinidine, diazepam, propranolol, metoprolol, sulfonylureas, verapamil, nifedipine, diltiazem, enalapril, and simvastatin.[33],[127] Although the patient is receiving rifampin, it may be necessary to monitor serum concentrations of the aforementioned drugs, when appropriate, or increase their dosages. Also, women who are taking rifampin and oral contraceptives should use an alternative method of birth control. When treating any patient with rifampin, the healthcare professional should carefully evaluate all concomitant medications for the possibility of drug–drug interactions.

Isoniazid–Rifampin

HEPATOTOXICITY

CASE 68-3, QUESTION 3: Will the combination of isoniazid and rifampin increase the risk of hepatotoxicity in C.M. to a greater extent than either drug alone?

Some initial evidence suggested that the concomitant use of isoniazid and rifampin was associated with a greater incidence of hepatotoxicity. The mechanism was thought to be attributable to rifampin induction of the metabolism of isoniazid to either monoacetylhydrazine or to other hepatotoxic products of hydrolysis. Steele et al.[123] performed a meta-analysis reviewing the incidence of hepatitis using regimens that contained isoniazid without rifampin, rifampin without isoniazid, and regimens containing both drugs. They found the incidence of clinical hepatitis was greater in regimens containing both isoniazid and rifampin (2.7%) versus regimens of isoniazid alone (1.6%), but this effect was additive, not synergistic, and therefore expected.[123] The use of the two drugs together, therefore, is not contraindicated, but caution should be used in high-risk groups such as the elderly, alcoholics, those receiving concomitant hepatotoxic agents, and those with preexisting liver disease.[117]

Ethambutol

OPTIC NEURITIS

CASE 68-4

QUESTION 1: S.E., a 65-year-old woman, was placed on isoniazid 300 mg/day, rifampin 600 mg/day, pyrazinamide 1,500 mg/day, and ethambutol 1,200 mg/day for initial treatment of active pulmonary TB. Two months after the initiation of therapy, she began to complain of blurred vision. A routine eye examination and visual field tests yielded a diagnosis of optic neuritis. No evidence was seen of glaucoma, cataracts, or retinal damage. Laboratory tests were within normal limits except for an elevated serum uric acid (9.7 mg/dL) and a slightly elevated serum creatinine (1.6 mg/dL). No symptoms of joint pain were associated with the elevated serum uric acid, and there was no history of gout. Her estimated creatinine clearance based on her weight of 65 kg was 36 mL/minute. Could the visual problem and increased uric acid levels be related to her medications?

S.E.'s decrease in visual acuity is compatible with ethambutol-induced optic neuritis. This condition is characterized by central scotomas, loss of red-green color vision, or less commonly, a peripheral vision defect. The intensity of these ocular effects is related to the duration of continued therapy after decreased visual acuity is first noted. Optic neuritis is related to both dose and duration, and it rarely occurs at doses of 15 mg/kg.[137–139] The incidence is estimated to be 6% for doses of 25 mg/kg and increases to 15% for doses in excess of 35 mg/kg. Recovery, which may take months, is usually, but not always, complete when the drug is discontinued.

Optic neuritis manifested in S.E. is probably caused by the use of an increased ethambutol dose (18.5 mg/kg) in a patient with impaired renal function. Because ethambutol adds no additional benefit to isoniazid and rifampin after the first 2 months for susceptible organisms, it can be discontinued. Ethambutol is excreted by the kidney (50%–80%), and her ethambutol dosing interval should have been increased based on the decline in creatinine clearance.[133] Her visual acuity should be monitored closely through periodic eye examinations, and she should be instructed to contact her physician immediately if she experiences any further visual changes.

S.E.'s elevated serum uric acid also may be attributed to her ethambutol as well as a decline in her renal function, but it is more likely caused by pyrazinamide, which decreases the tubular secretion of urate.[102] Asymptomatic hyperuricemia secondary to drugs usually does not require treatment.

SPECIAL TREATMENT CONSIDERATIONS

The Elderly

INCIDENCE

CASE 68-5

QUESTION 1: G.H., a 75-year-old, 80-kg man who resides in a nursing home, becomes disoriented, refuses to eat, and has a productive cough. Physical examination reveals a thin man with slight difficulty breathing. Laboratory findings are essentially normal with the exception of a slightly elevated blood urea nitrogen of 25 mg/dL and serum creatinine of 1.3 mg/dL. Chest radiography reveals infiltrates in the right lower lobe. He has a history of congestive heart failure, which is well controlled. Blood, urine, and sputum samples are sent for culture and susceptibility testing. The initial Gram stain is negative. Because the nursing home has recently had two cases of active TB, a PPD skin test and sputum smear for AFB are ordered. The PPD skin test induration is 16 mm, and the sputum smear is positive for AFB. G.H.'s admission skin test several months ago was negative. Discuss the presentation of TB in the elderly, and the appropriate treatment of active disease in G.H. Is the incidence of drug side effects higher in the elderly? Should other patients in close contact with G.H. receive isoniazid therapy?

In 2014, the overall case rate of TB in adults 64 years or older was higher than all other age-groups (4.8/100,000 population).[10] Similar to other age-groups, the case rate for persons 64 years or older has declined every year since 1993 when the case rate was 17.7/100,000 population.[10] In 2014, 2.2% of TB cases were reported in residents of long-term care facilities,[10] and the case rate for nursing home residents is 1.8 times higher than that for elderly persons living in the community.[140] Active TB disease in the elderly has been attributed to decreased immune function followed by reactivation of an earlier infection, but active disease is a common, endemic infection in nursing home patients with no previous immunity (negative skin test) to M. tuberculosis.[140],[141] The incidence of positive tuberculin skin tests increases after patients have been in the nursing home longer than 1 month. Therefore, all patients entering a nursing home should be tested with 5 TU of PPD. If the initial test is negative and a source case is present in the nursing home (as illustrated by this case), this test should be repeated in 1 month. The rate of tuberculin skin test conversion (from negative to positive tests) in this population is approximately 5%. If these recent converters are not treated with isoniazid, approximately 17% will develop progressive pulmonary TB.[142]

DIAGNOSIS

Diagnosis of active TB in elderly patients is difficult because classic symptoms of cough, fever, night sweats, and weight loss are often absent, and elderly patients may describe their symptoms poorly. The chest radiograph and PPD skin test may be the only signs of TB infection.[140],[142] Frequently, the chest radiograph is atypical, resembling pneumonia or worsening heart failure. Chest radiographs in the elderly are less likely to reveal upper lobe infiltration; however, more commonly they will show extensive infiltration of both lungs.[143] If the patient's clinical disease is caused by reactivation, the chest radiograph often shows apical infiltrates or nodules. If the disease is progressing from an initial infection, as in the case of G.H., lower lobe infiltrates may be present.[140] TB in this population may present clinically with changes in activities of daily living, chronic fatigue, cognitive impairment, anorexia, or unexplained low-grade fever. Nonspecific signs and symptoms that range in severity from subacute to chronic and that persist for weeks to months must alert clinicians to the possibility that unrecognized TB is present.[144] Sputum examination for M. tuberculosis, and AFB smear and culture should be performed in all patients, including the elderly.

TREATMENT OF ACTIVE DISEASE IN THE ELDERLY

The principles of TB treatment are the same for the elderly as for any other age-group.[33],[140] Because G.H. has clinical symptoms of a respiratory infection, positive sputum smears for AFB, and a positive tuberculin skin test, he should be treated with a four-drug regimen for active TB disease. Most TB cases in elderly patients are caused by drug-susceptible strains of M. tuberculosis; however, notable exceptions would be older patients who are from a country or region where the prevalence of drug-resistant strains is high, persons who have been inadequately treated in the past, or persons who acquired the infection from a recent contact known to be infected with drug-resistant M. tuberculosis.[144] G.H.'s drug regimen should include isoniazid 300 mg, rifampin 600 mg, pyrazinamide 2,000 mg, and ethambutol 1,600 mg daily for 8 weeks followed by isoniazid and rifampin daily or 2 to 3 times a week for 16 weeks (DOT). Another option might be isoniazid, rifampin, pyrazinamide, and ethambutol daily for 2 weeks, followed by twice weekly for 6 weeks, then isoniazid and rifampin twice weekly for 16 weeks.[144] Some clinicians prefer treating the elderly with 9-month regimens of isoniazid and rifampin. G.H. should also receive pyridoxine 10 to 50 mg with each dose.[66]

ADVERSE DRUG EFFECTS

Although isoniazid hepatitis is more common in elderly patients, both isoniazid and rifampin are generally well tolerated within this age-group, with major hematologic or hepatic side effects occurring in 3% to 4% of patients.[145] Therefore, serum aminotransferases should be assessed at baseline, and G.H. should be observed monthly for clinical signs of hepatitis. As discussed earlier, routine monitoring of LFTs remains controversial because transient, asymptomatic elevations do occur among the elderly.[145]

Although uncommon at 600 mg, rifampin given twice weekly may cause a greater incidence of flu-like symptoms. Because potential drug interactions with isoniazid and rifampin are possible, any medication added to the patient's regimen should be carefully

---

evaluated. Considering that G.H. has age-related decreased renal function, signs of ethambutol-induced visual dysfunction should be monitoring carefully.

TREATMENT OF LATENT INFECTION IN THE ELDERLY

Treatment of elderly patients with positive tuberculin skin tests but no active TB disease with isoniazid 300 mg daily for 6 to 9 months is essential if a source case is present in the nursing home. Stead et al.[142] reported only one case of active disease in patients receiving therapy for latent TB infection compared with 69 cases in untreated patients. In patients with recently converted skin tests, one patient in the group receiving isoniazid therapy had active disease compared with 45 who received no treatment.[142] Daily rifampin for 4 months or weekly isoniazid plus rifapentine for 12 weeks are also acceptable regimens in the elderly.[116,140]

Multidrug-Resistant Organisms

DEFINITION AND ETIOLOGY

CASE 68-6

QUESTION 1: M.S., an ill-appearing 29-year-old Asian man, is admitted to the hospital with signs and symptoms of pneumonia. He is coughing, and his chest radiograph indicates bilateral infiltrates. He is placed in respiratory isolation pending the results of sputum testing for M. tuberculosis. He states that he was diagnosed with TB approximately 3 months ago, and treatment was initiated with isoniazid, rifampin, pyrazinamide, and ethambutol. However, he stopped taking his medication after 1 month. An HIV test was performed 3 months ago, which was negative. What is the likelihood of acquired drug resistance in M. tuberculosis?

In the United States, isoniazid resistance was 18.9% and resistance to both isoniazid and rifampin was 7.1% in patients with previous TB in 2014.[10] Resistance in M. tuberculosis is either primary or acquired. Primary drug resistance occurs when a patient harbors a resistant strain before any drugs have been administered. Acquired drug resistance occurs when resistant subpopulations are selected as a result of treatment errors, such as addition of a single drug to a failing regimen, inadequate primary regimen, failure to recognize resistance, and, most importantly, nonadherence to the prescribed regimen. Sporadic ingestion, inadequate dosages, or malabsorption of medications can cause susceptible M. tuberculosis strains to become resistant to multiple drugs within a few months.[146,147] These resistant organisms can then be transmitted to persons who have never received treatment and lead to primary resistance in those patients.

M.S. is a foreign-born person of Asian ethnicity and may have primary resistance from his country of origin, making a detailed exposure history essential for the treatment of his infection. M.S. is also an example of the problem of treatment failure caused by nonadherence and the potential development of drug-resistant organisms. Homelessness and lack of awareness of the severity of TB have been shown to be significantly associated with interruptions in TB therapy.[148] Therefore, educational efforts to improve a patient's understanding of TB disease are critical for appropriate treatment of the disease.

Many factors can affect the outcome of therapy for MDR-TB, including HIV status, treatment adherence, the number of drugs to which the tubercle bacilli remain susceptible, and the time since the first diagnosis of TB.[149–151] In one study, all 11 patients who were HIV positive died during observation.[150] In another study, 77% of patients with MDR-TB had sputum cultures convert to negative in a median time of 60 days (range, 4–462 days), but 23% of patients never converted to negative cultures.[151] Of the patients who converted, 60% converted after 4 months of therapy.[151] Predictors of a longer time for sputum culture conversion were high initial sputum colony counts, bilateral cavitation on chest radiograph, previous treatment of MDR-TB, and the number of drugs the initial isolate was resistant to at the beginning of therapy.[151]

CASE 68-6, QUESTION 2: Can M.S. be cured by drug therapy, and if so, how should he be treated?

Because his recent HIV test was negative, M.S. has a higher probability of treatment success. In HIV-negative patients, 32 (97%) of 33 patients with MDR-TB were cured, and these patients received an average of five second-line drugs.[150] Only one relapse occurred 5 years after treatment.[150] Therefore, M.S.'s current regimen should be re-evaluated, drug susceptibility testing should be determined, and the patient should be referred to a specialist or consultation at a specialized treatment center.[33] Molecular drug resistance testing should be performed to evaluate resistance to rifampin, which is a reliable surrogate for MDR-TB. Standard susceptibility testing methods should be performed for the other agents, although results may not be available for several weeks. If the rapid molecular test detects the presence of mutations to rifampin, the patient should then begin therapy for MDR-TB. However, there is no standard treatment regimen for MDR-TB. When revising a treatment regimen, at least three previously unused drugs to which the organism is susceptible should be used, and one of these agents should be injectable.[33] A new regimen should contain at least four drugs, possibly more, depending on disease severity and resistance pattern. Treatment should be given by DOT, and the recommended duration is 18 to 24 months.[33],[149] However, only 40% of patients with MDR-TB complete a full 18 to 24 months of therapy.[152]

The efficacy of a standardized treatment regimen for a shorter duration of therapy was evaluated in patients with documented MDR-TB.[153] The study population consisted of 427 patients with a mean age of 34 years, 81.5% had bilateral disease on chest radiograph, and patients had exhibited TB for approximately 30 months on average. The mean body mass index was 16.1 kg/m^2, indicating severe emaciation. The intensive phase consisted of three or more months of therapy with six to seven agents, and doses were based on body weight.[153] Daily ofloxacin and gatifloxacin doses were 400, 600, and 800 mg for body weights less than 33 kg, 33 to 50 kg, and greater than 50 kg, respectively.[153] The most effective treatment regimen required a minimum of 9 months of therapy with gatifloxacin, clofazimine, ethambutol, and pyrazinamide throughout the treatment period with the addition of high-dose isoniazid, prothionamide, and kanamycin for a minimum of 4 months during the intensive phase. Among 206 patients receiving this regimen, the relapse-free cure rate was 87.9%. The most common adverse events with this regimen were vomiting (21.4%), diminished hearing acuity (6.3%), dysglycemia (3.9%), and ataxia (3.9%).[153] These results suggest that it may be possible to adequately treat patients with MDR-TB with shorter courses of therapy. However, prothionamide and kanamycin are unavailable in the United States.

Fluoroquinolones are active against mycobacteria, including M. tuberculosis, and they penetrate rapidly into macrophages and exhibit intracellular mycobactericidal activity.[149] Fluoroquinolones inhibit DNA gyrase in M. tuberculosis, but the other molecular target of these agents, topoisomerase IV, is absent.[149] Ciprofloxacin, ofloxacin, and levofloxacin have been used long term for the treatment of mycobacterial infections and were well tolerated with few serious adverse effects.[154],[155] Limited data suggest that moxifloxacin is an acceptable option in the treatment of MDR-TB.[156] Selection of fluoroquinolone resistance has been observed in vivo, and complete cross-resistance within the class is the accepted rule.[149] Other second-line medications used for MDR-TB include p-aminosalicylic acid, cycloserine, ethionamide, and capreomycin. These agents are associated with numerous side effects and should not be prescribed without the guidance of an expert in the treatment of MDR-TB.

Bedaquiline was FDA-approved in late 2012 as part of combination therapy with at least three or four other drugs in adults with pulmonary MDR-TB when other alternatives are not available. Bedaquiline is a novel drug that inhibits mycobacterial adenosine 5′-triphosphate synthase, thereby inhibiting energy production in M. tuberculosis.[157] The drug is available in 100 mg tablets, and the recommended dosage is 400 mg daily for 2 weeks followed by 200 mg thrice weekly for 22 weeks.[157] Bioavailability of bedaquiline is increased twofold when administered with food, and each dose should be administered by DOT.[157] Bedaquiline is metabolized by CYP3A4, and it is recommended to avoid concomitant administration of bedaquiline with moderate (e.g., efavirenz) and strong (e.g., rifamycins) CYP3A4 inducers. Strong CYP3A4 inhibitors may increase systemic exposure and adverse events of bedaquiline, and use of strong CYP3A4 inhibitors for more than 14 consecutive days should be avoided while the patient is receiving bedaquiline.[157] Bedaquiline can cause QT prolongation, and additive prolongation may occur with other drugs known to prolong the QT interval.

Bedaquiline received accelerated FDA approval based on the surrogate marker of time to sputum culture conversion in phase 2 studies. In the first study, 47 patients with MDR-TB received bedaquiline or placebo added to a preferred background regimen of kanamycin, ofloxacin, ethionamide, pyrazinamide, and cycloserine or terizidone for 8 weeks.[158] After 8 weeks, the background regimen was continued for a total of 96 weeks. Time to sputum culture conversion was significantly reduced in the bedaquiline group, and sputum cultures were negative in 48% of patients in the bedaquiline group compared to 9% in the placebo group at 8 weeks.[158] After 24 weeks, 81% of patients in the bedaquiline group had negative sputum cultures compared to 65.2% in the placebo group.[159] However, after 104 weeks, treatment success was achieved in 52.4% and 47.8% of patients in the bedaquiline and placebo groups, respectively.[159]

In the second study, 160 patients with pulmonary MDR-TB received either placebo or bedaquiline 400 mg daily for 2 weeks followed by 200 mg thrice weekly for 22 weeks with the same background regimen described previously.[160] After 24 weeks, patients continued the background regimen for a total of 18 to 24 months. The median time to sputum culture conversion was 83 days in the bedaquiline group compared to 125 days in the placebo group ($p < 0.001$).[160] Compared to placebo, significantly more patients in the bedaquiline group had negative cultures at 24 weeks (79% vs. 62%, $p = 0.008$) and at 120 weeks (62% vs. 44%, $p = 0.04$).[160] However, mortality was significantly higher in patients receiving bedaquiline (13% vs. 2%, $p = 0.02$).[160]

Human Immunodeficiency Virus Infection

TREATMENT OF ACTIVE DISEASE

CASE 68-7

QUESTION 1: F.R. is a 32-year-old man who presents to the emergency department complaining of mild pleuritic chest pain and a productive cough. He also has experienced weight loss, fatigue, and night sweats for the past 3 weeks. On questioning, F.R. states that he is bisexual and frequently engages in unprotected sex. Chest radiography reveals bilateral interstitial infiltrates. Sputum samples are ordered, and the workup includes AFB smear and culture. A PPD skin test is placed, and an HIV test is ordered. The results of the AFB smear and HIV test are positive, and the induration from the PPD is 6 mm. A $CD4^+$ count is ordered, which is 150 cells/μL. What are the clinical manifestations of active TB in patients infected with HIV? How effective is skin testing in the diagnosis of TB infection in patients infected with HIV? What diagnostic tests should be performed in F.R.?

HIV infection is an important risk factor for active TB disease because HIV infects and destroys $CD4^+$ cells, leading to impaired cell-mediated immunity. The immunodeficiency allows for rapid development of active TB disease in a person who is infected with M. tuberculosis. TB is a common opportunistic infection in persons infected with HIV, but unlike other opportunistic infections in this population, $CD4^+$ cell count is not a reliable predictor for risk for TB disease.[65] Active TB disease can occur at any $CD4^+$ cell count, but the risk increases as a patient's immunodeficiency progresses.[161]

Common symptoms of active disease (productive cough, fever, sweats, weight loss, fatigue) may be present in HIV-infected individuals, but the clinical manifestations of TB depend on the severity of the immunodeficiency at the time of presentation. TB in an HIV-infected person will clinically resemble TB in an HIV-uninfected person if the immunodeficiency is less severe ($CD4^+$ count >350 cells/μL).[65],[161] The disease will primarily be limited to the lungs in these patients, and upper lobe involvement with or without cavitation will be seen on chest radiography. However, the findings on chest radiography are markedly different in patients with advanced HIV disease. Lower lobe, middle lobe, interstitial, and miliary infiltrates are common, whereas cavitation is seen infrequently.[65],[161] In these patients, TB may be difficult to distinguish from other HIV-related pulmonary opportunistic infections (Pneumocystis jiroveci, M. avium complex), and TB should be ruled out in any HIV-infected patient with pulmonary symptoms. Patients with advanced HIV disease may also have normal chest radiographs but still have positive sputum smears for AFB and positive cultures for M. tuberculosis.[161] Therefore, a normal chest radiograph does not exclude the possibility of active TB disease. Extrapulmonary TB is more common in HIV-infected persons with $CD4^+$ counts less than 200 cells/μL.[65],[161] Because of F.R.'s clinical presentation and positive HIV test, a high index of suspicion and diagnostic workup for active TB are appropriate.

A PPD skin test should be placed on HIV-infected patients with suspected TB infection, but sensitivity and specificity of skin testing are poor in patients with HIV infection. Only about 30% to 50% of patients with AIDS and TB will respond to a PPD skin test with an induration greater than 10 mm. Therefore, an induration of 5 mm or more is considered to be a positive reaction in this population.[48],[161] F.R.'s reaction of 6 mm to the tuberculin skin test should be considered positive. Theoretically, the sensitivity and specificity of IGRAs are also limited in patients with HIV infection because the tests depend on adequately functioning $CD4^+$ cells. In a study of 294 HIV-infected subjects, indeterminate results were more likely to occur in subjects with a $CD4^+$ count less than 100 cells/μL compared with those with a $CD4^+$ count of 100 cells/μL or more.[162] Additional studies found only 64% sensitivity for detection of active TB disease, and false-negative results occurred in approximately 25% of HIV-infected patients with documented pulmonary TB.[163],[164] These studies suggest that IGRAs should not be used alone to exclude active TB in this population.

The diagnostic workup for HIV-infected persons is similar to that for HIV-uninfected persons. Chest radiography and sputum samples for AFB smear and culture of three sputum specimens should be obtained.[161],[165] NAA tests can be used to assist in evaluation of HIV-infected persons with positive AFB smears, and a positive NAA result in a patient who is AFB smear positive likely represents active TB.[65],[161] Drug susceptibility testing for all first-line agents should be performed on the initial isolate for all patients, and testing should be repeated if sputum cultures remain positive after 4 months of treatment or become positive after at least 1 month of negative cultures.[161] Susceptibility testing of second-line agents should be limited to specimens from patients who have received prior therapy, are contacts of persons with drug-resistant TB disease, have demonstrated resistance to rifampin or other first-line agents, have positive cultures after

---

3 months of therapy, or are from regions with a high prevalence of MDR-TB or XDR-TB.[166] Molecular drug resistance tests may also be used to yield faster results. Patients with symptoms of extrapulmonary TB should undergo needle aspiration or tissue biopsy of skin lesions, lymph nodes, or pericardial or pleural fluid, and blood cultures for AFB should be obtained.[65]

CASE 68-7, QUESTION 2: What is the preferred treatment regimen for TB in F.R.?

Given his symptoms and positive AFB smear, F.R. should be started on multiple-drug therapy for treatment of active TB disease. DOT is recommended for all patients with HIV-related TB.[33],[65],[161] F.R.'s treatment plan should be based on completion of the total number of doses ingested rather than the duration of therapy. Principles and recommendations for treatment of TB in HIV-infected adults are similar to those for HIV-uninfected adults, with a notable exception (Table 68-2). The initial 8-week treatment phase in F.R. should include isoniazid, rifampin or rifabutin, pyrazinamide, and ethambutol administered daily by DOT (7 days/week for 56 doses or 5 days/week for 40 doses).[33],[65] However, twice- or thrice-weekly dosing regimens during the intensive phase have been associated with increased risk of treatment failure or relapse with acquired rifamycin resistance; therefore, intermittent dosing regimens are no longer recommended during the intensive phase.[161] F.R. should also receive supplemental pyridoxine. After the initial phase, if no drug resistance is evident on susceptibility or molecular testing, F.R. can be treated with isoniazid and rifampin (or rifabutin) daily or 2 to 3 times a week by DOT for a minimum of 26 weeks.[65] Although not applicable to F.R. because his CD4$^+$ cell count is 150 cells/μL, it should be noted that twice-weekly continuation therapy with isoniazid and rifampin or isoniazid and rifabutin is not recommended for HIV-infected patients with a CD4$^+$ count less than 100 cells/μL because of an increased frequency of acquired rifamycin resistance.[33],[65],[167],[168] Twice-weekly administration in the continuation phase may be considered in F.R. because his CD4$^+$ count is greater than 100 cells/μL, but the data supporting this recommendation are limited (Table 68-2).[33],[65] In addition, the once-weekly continuation regimen of isoniazid and rifapentine is contraindicated in HIV-infected patients because of a high rate of relapse with organisms that have acquired resistance to the rifamycins.[33],[65]

A randomized clinical study evaluated the efficacy of 6 months and 9 months of fully intermittent therapy in HIV-infected patients with TB.[169] All patients received 2 months of isoniazid, rifampin, pyrazinamide, and ethambutol, and then patients were randomly assigned to receive either 4 months ($n = 167$) or 7 months ($n = 160$) of isoniazid and rifampin. Throughout the study duration, doses were administered thrice weekly. The median viral load was 155,000 copies/mL, and the median $CD4^+$ cell count was 160 cells/μL. Favorable clinical response was similar between the two groups; however, bacteriologic recurrence occurred significantly less frequently in the 9-month group compared with the 6-month group (7% vs. 15%; $p < 0.05$).[169] These data may provide support for 9 months of therapy if a fully intermittent regimen is prescribed for TB therapy in HIV-infected patients.

CASE 68-7, QUESTION 3: How should TB therapy be monitored in F.R.?

If F.R. had cavitary disease on chest radiography or if cultures are positive after 2 months of therapy, treatment with isoniazid and rifampin or rifabutin should be continued to complete a total of 9 months of therapy. If F.R. was suspected of having extrapulmonary disease caused by drug-susceptible strains, the recommended treatment is isoniazid, rifampin, pyrazinamide, and ethambutol for 2 months followed by isoniazid and rifampin for 4 to 7 months. However, longer durations of therapy are recommended for extrapulmonary TB involving the CNS (meningitis or tuberculoma) or bone and joints. For these infections, many experts recommend 9 to 12 months of therapy.[65],[161]

Baseline and monthly evaluations of hepatic function, renal function, complete blood count, and $CD4^+$ cell count are recommended in all HIV-infected patients with active TB disease.[65] In the absence of symptoms, elevations of AST <3 times the upper limit of normal should not cause a change in therapy.[161] If the AST is >3 times the upper limit of normal in a patient with symptoms, >5 times the upper limit of normal regardless of symptoms, or if a significant increase in alkaline phosphatase and/or bilirubin occurs, hepatotoxic drugs should be stopped and the patient evaluated.[161] For pulmonary TB, at least one sputum specimen should be obtained monthly for AFB smear and culture until two consecutive specimens are culture negative.[65],[161] If the AFB smear is positive at the initiation of treatment, AFB smears may be obtained every 2 weeks to provide an early assessment of bacteriologic response to therapy.[33],[65] Results of sputum samples obtained after the initial 8-week treatment phase are important because determination of the duration of the continuation phase will be based on these results. Susceptibility testing should be performed on all isolates, and susceptibility testing should be repeated on a newly obtained sputum sample if cultures are positive for M. tuberculosis after 3 months of therapy.[65] Patients with positive cultures at or after 4 months of therapy should be considered treatment failures.

At every visit, patients should be questioned about adherence to therapy and possible adverse events to the treatment regimen. If a patient is experiencing adverse events, the first-line drugs should not be discontinued permanently without strong evidence that a specific agent is the cause of the adverse event.[65],[161] Drug concentration monitoring may be useful to help guide therapy in patients who respond slowly to the prescribed treatment regimen.[170]

CASE 68-7, QUESTION 4: When should antiretroviral therapy (ART) be initiated in F.R.?

Optimal management of active TB disease in patients infected with HIV requires treatment of both infections. Sequential treatment of TB followed by treatment of HIV is not recommended.[161] In patients with HIV infection, $CD4^+$ cells multiply in response to M. tuberculosis, and then HIV replication accelerates within the lymphocytes and macrophages, which leads to progression of HIV disease. Therefore, initiation of ART can prevent progression of HIV disease and reduce morbidity and mortality associated with TB and other opportunistic infections.[65],[161] However, this approach may be associated with cumulative drug toxicities, significant drug interactions, a higher pill burden, and the potential for development of immune reconstitution inflammatory syndrome (IRIS).[65],[161]

Three studies addressed the optimal timing to initiate ART during the treatment of active TB disease.[171–173] In ART-naïve patients, ART should be initiated within 2 weeks of starting TB therapy in patients with a $CD4^+$ count less than 50 cells/μL. Early initiation of ART significantly reduces mortality in these patients, but the risk of IRIS is increased. In patients with $CD4^+$ counts of 50 cells/μL or greater who present with severe TB disease (low Karnofsky score, low body mass index, low hemoglobin, low albumin, organ system dysfunction, or extensive disease), ART should be initiated within 2 to 4 weeks of starting TB therapy. In patients with $CD4^+$ counts of 50 cells/μL or greater who do not have severe TB disease, ART should be initiated within 8 to 12 weeks of initiating TB therapy.[171–173] If IRIS develops, neither therapy for TB nor HIV should be discontinued. Because F.R. is ART naïve and his $CD4^+$ count is 150 cells/μL, ART should be initiated within 8 to 12 weeks of starting treatment for active TB.

If F.R. was receiving ART when diagnosed with TB, treatment for TB should be started immediately, and ART should be modified to maintain virologic suppression while reducing the risk for drug–drug interactions.[161] ART should not be withheld simply because the patient is being treated for TB, and a rifamycin should not be excluded from the treatment regimen for fear of interactions with certain antiretroviral agents.[33],[174] Exclusion of a rifamycin will likely delay sputum conversion, prolong the duration of therapy, and possibly result in a poor outcome.

CASE 68-7, QUESTION 5: Because F.R.'s $CD4^+$ count is 150 cells/μL, the decision is made to begin ART after the initial 8-week intensive phase to decrease the potential for IRIS. What is IRIS? What drug interactions are likely in an HIV-infected patient receiving treatment for TB and HIV?

Immune reconstitution inflammatory syndrome, or IRIS, occurs in approximately 30% of patients who begin therapy for both HIV and TB in close temporal proximity.[161],[174] This syndrome is thought to reflect recovery of immune responses to M. tuberculosis and usually occurs in the first 1 to 4 weeks after initiation of ART.[161] IRIS lasts for 2 to 3 months on average, but some patients may experience IRIS symptoms for months. The immune response can be an exaggerated inflammatory response during TB therapy in a patient known to have TB infection, or it may unmask a previously undiagnosed TB infection. The risk of IRIS is greater when ART is initiated within the first 2 months of TB therapy and when the $CD4^+$ count is less than 100 cells/μL.[65],[161] Symptoms include high fever, malaise, and local reactions in organs, depending on the location of the mycobacterial infection (e.g., lungs, lymph nodes, CNS). IRIS is usually self-limiting, but supportive therapy may be required if symptoms are severe. Moderate IRIS reactions should be treated with nonsteroidal anti-inflammatory drugs without any changes to TB therapy or ART.[65] No specific treatment recommendations are available for severe IRIS; however, prednisone or methylprednisolone at doses of 1 mg/kg body weight and tapered for 1 to 2 weeks has been beneficial.[65]

Simultaneous treatment of TB and HIV can be complicated by drug interactions with the rifamycins and ART.[135],[161] Rifampin is a potent inducer of cytochrome P450 isoenzymes, but rifabutin is not a potent inducer.[33],[35],[65] Rifabutin is highly active against M. tuberculosis, and data from clinical trials suggest equal efficacy with rifampin- and rifabutin-based treatment regimens.[33],[161] Because of fewer drug interactions and documented efficacy, rifabutin is recommended in place of rifampin for the treatment of active TB in HIV-infected patients receiving certain protease inhibitors or NNRTIs.[33],[161] However, some antiretroviral agents may either induce or inhibit cytochrome P450 isoenzymes, depending on the specific drug, and may alter rifabutin serum concentrations.[33],[167]

For the NNRTIs, rifampin was shown to decrease efavirenz exposures by 26%, but two additional studies did not show a significant effect of rifampin on efavirenz exposure.[175–177] Therefore, the preferred treatment regimens are rifampin-based TB therapy with an ART regimen consisting of efavirenz plus two nucleoside reverse transcriptase inhibitors.[161] The efavirenz dose should be 600 mg daily.[161] Efavirenz decreases rifabutin exposure by 38%, necessitating a dosage increase for rifabutin to 450 to 600 mg daily.[161] For patients unable to take efavirenz due to early pregnancy or intolerance, nevirapine-based ART can be used, but rifampin significantly decreases nevirapine exposures.[161] If used concomitantly, the nevirapine dose should be 200 mg twice daily.[161] However, rifabutin-based TB therapy may be considered with a nevirapine-based ART regimen because dosage adjustments are not needed for either agent.[161] Concomitant administration of etravirine and rilpivirine with rifampin should be avoided due to significant reduction in exposures of these NNRTIs.[161]

Rifampin should not be used in patients receiving protease inhibitor-based ART, regardless of boosting with ritonavir, because rifampin causes a dramatic decrease in exposures of the protease inhibitors.[65],[161] Rifabutin has a negligible effect on ritonavir-boosted lopinavir or atazanavir and only moderate increases in darunavir and fosamprenavir concentrations.[161] For patients unable to tolerate efavirenz or nevirapine or if the HIV strain is resistant to NNRTIs, a rifabutin-based TB regimen is preferred with an ritonavir-boosted protease inhibitor regimen.[161] However, all protease inhibitors markedly increase rifabutin concentrations. If doses of rifabutin are not adjusted, adverse drug events, such as uveitis, neutropenia, arthralgias, skin discoloration, may occur.[65],[167] Therefore, the rifabutin dose should be decreased to 150 mg daily when administered with protease inhibitors.[161]

HIV nucleoside and nucleotide reverse transcriptase inhibitors and the fusion inhibitor enfuvirtide are not metabolized by CYP isoenzymes. As a result, these agents can be administered with the rifamycins.[135] Rifampin decreases the concentrations of the integrase inhibitors, raltegravir and elvitegravir. The raltegravir dose should be increased to 800 mg twice daily, but no dosage adjustment is recommended with rifabutin.[161] Co-administration with elvitegravir with rifampin and rifabutin should be avoided.[161] Maraviroc, a CCR5 antagonist, is a substrate for CYP3A and P-glycoprotein, and concomitant administration with rifampin significantly decreases exposures.[135] The maraviroc dose should be increased to 600 mg twice daily, but no dosage adjustment is needed with rifabutin.[161]

TREATMENT OF LATENT TUBERCULOSIS INFECTION IN HUMAN IMMUNODEFICIENCY VIRUS INFECTION

CASE 68-8

QUESTION 1: N.M. is the 32-year-old partner and roommate of F.R. Because of his close contact with F.R., he is evaluated for exposure to TB by an infectious diseases specialist. N.M.'s HIV test is positive, and a tuberculin skin test produces an induration of 8 mm, which is positive. All other studies are negative for active TB. Should N.M. receive treatment for latent TB infection? If so, what therapy should he receive?

The risk of N.M. developing active TB disease is significant; therefore, he should receive treatment for latent TB infection. HIV-infected persons, regardless of age, should be treated for latent TB infection.[65] Pape et al. conducted a randomized, placebo-controlled trial of isoniazid therapy in HIV-infected patients.[178] Patients receiving placebo were 6 times more likely to develop active TB than those receiving isoniazid, and patients receiving isoniazid were also less likely to develop AIDS.[178] The preferred treatment for latent TB infection in N.M. is isoniazid 300 mg daily or twice weekly for 9 months.[65],[161] Isoniazid does not increase the risk of hepatitis when used with efavirenz- or nevirapine-based ART regimens.[161] N.M. should also receive pyridoxine 25 mg daily to prevent peripheral neuropathy. Rifampin and rifabutin for 4 months are alternatives to isoniazid, but the potential for drug interactions should be considered. Weekly isoniazid plus rifapentine are not recommended for HIV-infected patients due to the potential for significant drug interactions with rifapentine and ART.[161]

Pregnancy

CASE 68-9

QUESTION 1: E.F. is a 25-year-old Hispanic woman who is being treated with isoniazid 900 mg and rifampin 600 mg twice a week for pulmonary TB. She completed 2 months of therapy with isoniazid, rifampin, pyrazinamide, and ethambutol, and began the new regimen 2 months ago. She recently became pregnant, and her obstetrician is concerned about the possible teratogenic effects of her TB regimen. What are the risks of TB and its treatment to the mother and the fetus? Are these drugs teratogenic?

Although concerns about the use of any medication during pregnancy always exist, it is now recognized that untreated TB represents a far greater risk to a pregnant woman and her fetus than the treatment.[33],[66] TB is one of the leading nonobstetric causes of maternal mortality.[179] The World Health Organization recommends that treatment of TB in pregnant women should be the same as that for nonpregnant women, with few exceptions.[179] Isoniazid, rifampin, pyrazinamide, and ethambutol are not teratogenic in humans.[180],[181] In the United States, pyrazinamide is not recommended for use during pregnancy because of insufficient safety data.[33] If pyrazinamide is not included in the initial treatment regimen, the minimal duration of therapy is 9 months.[33] All pregnant women receiving isoniazid should also receive pyridoxine 25 mg/day because of the possibility of peripheral neuropathy.

Streptomycin should not be used during pregnancy except as a last alternative because it has been associated with mild-to-severe ototoxicity in the fetus.[179] Ototoxicity can occur throughout the gestational period and is not confined to the first trimester. With the exception of streptomycin ototoxicity, the occurrence of birth defects in women being treated for TB with the above agents is no greater than that of healthy pregnant women.[182],[183] Therefore, administration of antituberculosis drugs is not an indication for termination of pregnancy.[33] Because E.F. likely became pregnant after completing the first 2 months of therapy, she should continue her current regimen for a total of 6 months because she received pyrazinamide as part of the initial regimen.

MULTIDRUG-RESISTANT TUBERCULOSIS IN PREGNANCY

Little is known about the efficacy and safety of second-line drugs for the treatment of MDR-TB during pregnancy. Two reports with small numbers of patients have suggested that treatment is effective with no adverse effects to mother or child.[184],[185] In a study of seven women treated for MDR-TB during pregnancy, no obstetric complications or perinatal transmission of MDR-TB was observed.[184] Five women were cured, one experienced treatment failure, and one stopped therapy prematurely.[184] No evidence of drug toxicity was seen among their children exposed to second-line drugs in utero, although one child was diagnosed with MDR-TB.[185] There are no well-controlled studies with bedaquiline in pregnancy; therefore, the drug should only be used in pregnancy if clearly needed. More data are needed, but pregnancy should not be a limitation to the treatment of MDR-TB.

LACTATION

When the baby is born, E.F. may breast-feed while continuing her medication. Drug concentrations in breast milk are minimal and do not provide sufficient quantities for the treatment or prevention of TB in the nursing infant.[33],[66]

Pediatrics

CASE 68-10

QUESTION 1: A.M., a 3-year-old African American boy, is suspected of having TB. His father has been receiving treatment for TB for the last 2 months. A.M. has a productive cough, fever, and general malaise. His sputum is positive for AFB, and his PPD skin test is positive (10 mm). What is the incidence of TB in children? How should A.M. be treated?

The incidence of TB in children younger than 15 years of age has declined from 1,660 cases (2.9/100,000 population) in 1993 to 460 cases (0.8/100,000 population) in 2014.[10] Children commonly have active TB disease as a complication of the initial infection with M. tuberculosis, and the disease is characterized by intrathoracic adenopathy, middle and lower lung lobe infiltrates, and the absence of cavitation on chest radiography.[33],[186] Because of the high risk of disseminated TB in infants and children, treatment should be started as soon as the diagnosis of TB is suspected. In general, regimens recommended for adults are also recommended for infants, children, and adolescents, with the exception that ethambutol is not used routinely in children.[33] Ethambutol is often avoided because it is difficult to assess visual acuity in children. A.M. should be started on isoniazid 10 to 15 mg/kg/day, rifampin 10 to 20 mg/kg/day, and pyrazinamide 15 to 30 mg/kg/day.[33],[66],[186] Many experts prefer to treat children with three drugs (rather than four) in the initial phase because the bacillary population is usually lower than in an adult and it may be difficult for an infant or child to ingest four drugs. If resistance is suspected, ethambutol 15 to 20 mg/kg/day or streptomycin 20 to 40 mg/kg/day should be added to the regimen until susceptibility of the organism to isoniazid, rifampin, and pyrazinamide is known. Pyridoxine is recommended for infants, children, and adolescents who are receiving isoniazid.[33]

If resistance is not suspected and drug susceptibility is confirmed, A.M. should receive the isoniazid, rifampin, and pyrazinamide daily for 8 weeks. He can then continue to take the isoniazid and rifampin daily or 2 to 3 times a week (DOT) for an additional 4 months. The dosage for isoniazid and rifampin in a 2 to 3 times a week regimen would be 20 to 30 mg/kg/dose and 10 to 20 mg/kg/dose, respectively (Table 68-3).

A.M. should be examined routinely for signs and symptoms of hepatitis. Although antituberculosis medications are generally well tolerated in children, LFTs are commonly 2 to 3 times the upper limit of normal during therapy. These are often benign and transient; however, the incidence of hepatitis in children from isoniazid with rifampin may be 4 to 6 times more common than in children receiving isoniazid alone. Most hepatitis occurs within the first 3 months of therapy and generally is associated with higher than recommended doses of isoniazid or rifampin.[123],[187]

Children and adolescents should be screened for risk factors for TB using a questionnaire, and they should be skin tested with 5 TU of PPD if one or more risk factors are present.[188] Insufficient data are available to recommend use of IGRAs in children. Isoniazid for 9 months is recommended for treatment of latent TB in this population.[188] Daily rifampin for 6 months is an acceptable alternative, especially in children who cannot tolerate isoniazid or those exposed to a source case whose isolate was isoniazid resistant.[188]

Extrapulmonary Tuberculosis and Tuberculous Meningitis

CASE 68-11

QUESTION 1: R.U. is a 64-year-old, 82-kg man who is brought to the emergency department after a 4-day period during which

---

he became progressively disoriented, febrile to 40.5°C, and obtunded. He also had severe headaches during this time. Physical examination revealed moderate nuchal rigidity and a positive Brudzinski sign (neck resistant to flexion). An initial diagnosis of possible meningitis was made, and a lumbar puncture ordered. The cerebrospinal fluid (CSF) appeared turbid, and laboratory analysis revealed an elevated protein concentration of 200 mg/dL, a decreased glucose concentration of 30 mg/dL, and a white blood cell count of 500/μL (85% lymphocytes). A Gram stain of the spinal fluid and a sputum smear for AFB were negative, but the AFB smear of the CSF was positive. Other laboratory tests were within normal limits. A diagnosis of tuberculous meningitis was made. Discuss the presentation and prognosis of tuberculous meningitis. How should R.U. be treated?

Tuberculous meningitis is only one of the extrapulmonary complications of infection with M. tuberculosis.

Successful treatment of extrapulmonary TB can usually be accomplished in 6 to 9 months with an acceptable relapse rate.[33],[66],[189] Some forms, such as bone or joint TB, miliary TB, or tuberculous meningitis, may require 9 to 12 months of therapy.[33] Because specimens for culture and susceptibility testing may be difficult or impossible to obtain from a site, response to treatment must be based on clinical and radiographic improvement.

Tuberculous meningitis in older persons is usually caused by hematogenous dissemination of the tubercle bacilli from a primary site, most commonly the lungs. In its early stages, tuberculous meningitis often is confused with aseptic meningitis because the Gram stain is negative. The most common symptoms of tuberculous meningitis are headache, fever, restlessness, irritability, nausea, and vomiting. A positive Brudzinski sign and neck stiffness may be present. As illustrated in R.U., the CSF is usually turbid with increased protein and decreased glucose concentrations. There is an increase in the CSF white blood cell count with a predominance of lymphocytes. Culture of the CSF for M. tuberculosis may not be helpful because rates of positivity for clinically diagnosed cases range from 25% to 70%.[190] Early recognition and treatment are essential for a favorable outcome. Thus, empirical treatment before receipt of confirmatory culture and susceptibility results is common in suspected tuberculous meningitis. Multiple-drug therapy should be used because irreversible brain damage or death can occur as soon as 2 weeks after the onset of infection (not clinical symptoms).[190]

TREATMENT

Treatment should be initiated in R.U. with daily administration of isoniazid 300 mg, rifampin 600 mg, pyrazinamide 2,000 mg, and ethambutol 1,600 mg for the first 8 weeks.[33] After this initial phase of treatment, R.U. should receive daily isoniazid and rifampin for an additional 7 to 10 months, although the optimal duration of therapy is unknown.[33] In addition, because R.U. is older, pyridoxine 10 to 50 mg/day should be given to prevent the occurrence of peripheral neuropathy from isoniazid. It should be reiterated that rifampin can impart a red to orange color to the CSF.

Isoniazid readily penetrates into the CSF, with CSF concentrations reaching up to 100% of those in the serum. Rifampin is often included in tuberculous meningitis regimens and may be associated with reduced morbidity and mortality; however, even with inflammation, CSF concentrations of rifampin are only 6% to 30% of those found in the serum. Ethambutol should be used in the highest dosage to achieve bactericidal concentrations in the CSF because its CSF concentrations are only 10% to 54% of those in the serum. Streptomycin penetrates into the CSF poorly even with inflamed meninges.[191]

CORTICOSTEROIDS

Corticosteroids in moderate-to-severe tuberculous meningitis appear to reduce sequelae and prolong survival.[192] The mechanism for this benefit is likely owing to reduction of intracranial pressure. Dexamethasone 8 to 12 mg/day (or prednisone equivalent) for 6 to 8 weeks should be used and then tapered slowly after symptoms subside.[192] Corticosteroids are likely indicated for R.U.

THERAPEUTIC DRUG MONITORING

The pharmacokinetics of the drugs used to treat tuberculosis are highly variable and depend on weight, sex, genetic traits, and underlying comorbidities. Subtherapeutic concentrations may be associated with a delayed response to therapy, increased risk of relapse, or acquired drug resistance. Several studies measured drug concentrations in patients with slow clinical response to TB treatment and found subtherapeutic concentrations for isoniazid, rifampin, ethambutol, and rifabutin in a substantial percentage of patients evaluated.[87],[193–195] In one study, time to sputum culture conversion was longer in patients with low serum concentrations.[195] In a prospective observational study, 2-hour plasma concentrations were measured in 35 patients, and plasma concentrations were below the normal ranges in 71%, 58%, 46%, and 10% of patients for isoniazid, rifampin, ethambutol, and pyrazinamide, respectively.[196] In addition, 45% of patients had subtherapeutic concentrations for both isoniazid and rifampin. Treatment failure occurred significantly more frequently when concentrations of isoniazid and rifampin were below the normal ranges ($p = 0.013$) and below the median 2-hour drug concentration achieved in the study ($p = 0.005$).[196] In 142 patients with active TB, poor long-term outcomes were predicted by a 24-hour area under the concentration–time curve (AUC) ≤363 mg × hour/L for pyrazinamide, ≤13 mg × hour/L for rifampin, and ≤52 mg × hour/L for isoniazid.[197] Poor outcomes occurred in 32/78 patients with at least one drug with an AUC below these threshold values compared to 3/64 patients without any low AUCs (odds ratio = 14.14; 95% CI 4.08–49.1). Low rifampin and isoniazid peak concentrations and AUCs predicted acquired drug resistance in all cases.[197]

Based on these studies, therapeutic drug monitoring may be useful in patients with poor or slow clinical response to therapy and allow for dosage adjustment to achieve therapeutic drug concentrations. Additional patients who may benefit from therapeutic drug monitoring include those with severe disease, diabetes, HIV infection, renal dysfunction, and hepatic dysfunction.[198] A 2-hour postdose blood sample can be obtained to estimate the peak concentration for most drugs, whereas a 3-hour postdose blood sample would be needed for rifabutin.[198] A second blood sample at 6 hours postdose (7 hours for rifabutin) may also be obtained. Trough concentrations for most agents are below the detection limit of the assays at the end of a dosing interval and are not useful clinically.[198] Blood samples should be collected in red-top test tubes and processed promptly because some drugs are not stable at room temperature in blood or serum. Once the drug concentrations are known, comparisons can be made to the normal ranges for each drug and doses adjusted accordingly. However, normal ranges for drug concentrations have not been studied in regard to clinical outcome, and optimal drug concentrations for clinical and microbiologic efficacy are not known.[196] Although therapeutic drug monitoring may provide useful information, clinicians must remember that serum concentrations are only one factor among multiple factors affecting treatment outcomes.

Infectious Diarrhea

Gail S. Itokazu and David T. Bearden

CORE PRINCIPLES

		CHAPTER CASES
①	The most common complication of any diarrheal illness is loss of fluids and electrolytes, which in extreme cases can lead to hypovolemia, shock, and death. Depending on the degree of dehydration, fluid and electrolyte losses are replaced intravenously or orally.	**Case 69-1 (Questions 1, 2)**
②	Classification of infectious diarrheas as either an inflammatory or noninflammatory diarrheal illness provides a basis for preparing a focused list of suspected pathogens, thus guiding the overall diagnostic and therapeutic plan.	**Case 69-1 (Questions 3–4)**
③	Vibrio cholerae 01 and 0139 are toxigenic strains of Vibrio species, which cause epidemic cholera; severe dehydration requiring vigorous fluid replacement may be necessary. Non-cholera Vibrio species do not possess the virulence factors required to cause epidemic cholera. Antimicrobial treatment differs between toxigenic and non-toxigenic Vibrio species.	**Case 69-2 (Questions 1–3),** **Case 69-3 (Questions 1, 2)**
④	Salmonella species are classified as non-typhoidal and typhoidal salmonellae. Non-typhoidal salmonellae may cause the clinical syndromes of gastroenteritis, bacteremia, and localized infection, whereas typhoidal salmonellae may cause typhoid fever and chronic carriage. The role of antimicrobials in the management of salmonellosis is based on the clinical syndrome, its severity, and underlying health problems of infected persons.	**Case 69-7 (Question 1),** **Case 69-8 (Questions 1, 2),** **Case 69-9 (Question 1),** **Case 69-10 (Question 1),** **Case 69-11 (Questions 1–7)**
⑤	Severe dysentery caused by Shigella species is most commonly caused by Shigella dysenteriae, whereas a milder illness is typically caused by Shigella sonnei. Antimicrobials alleviate the symptoms of shigellosis, and decrease the period of time that shigellae can be spread by person-to-person contact.	**Case 69-12 (Questions 1–5),** **Case 69-13 (Question 1)**
⑥	Fluoroquinolone-resistance in Campylobacter species is a common finding in both developed and underdeveloped areas of the world; when indicated, macrolide antimicrobials are recommended.	**Case 69-14 (Questions 1–3)**
⑦	Travelers to destinations where acquisition of Travelers' diarrhea (TD) is a concern should bring a travel kit including medications (e.g., loperamide and antimicrobials) and instructions for self-treatment at the onset of illness. The selected antimicrobial depends on the area of	**Case 69-15 (Questions 1–6)**

	travel. Long-term postinfectious complications of TD may occur in some returning travelers.	
8	Escherichia coli O157:H7 is a specific toxin-producing strain of E. coli bacteria that can lead to the severe sequelae of hemolytic uremic syndrome.	**Case 69-16 (Questions 3, 4)**
9	Clostridium difficile infection causes a wide range of severity of illness. Mild-to-moderate disease is typically treated with metronidazole as first-line therapy, and oral vancomycin is preferred for severe disease.	**Case 69-17 (Question 6)**
10	Severe C. difficile infection can be life-threatening and often necessitates multiple therapeutic interventions.	**Case 69-18 (Questions 4, 5)**

PREVALENCE AND ETIOLOGY

Worldwide, diarrhea accounts for more than 2.5 million deaths annually,[1] mainly affecting infants and children living in poverty.[2] Prolonged episodes of diarrhea lead to malnutrition and in children contribute to impaired growth and developmental delay.[2] In the United States, about 48 million foodborne diarrheal illnesses occur each year, resulting in 128,000 hospitalizations and 3,000 deaths.[3]

Infectious diarrhea is caused by the ingestion of food or water contaminated with pathogenic microorganisms (e.g., bacteria, viruses, protozoa, or fungi) or their toxins (Table 69-1).[2] In the United States, noroviruses account for about 50% of diarrheal outbreaks, while common bacterial pathogens include Campylobacter, non-typhoidal Salmonella, Shigella, and Shiga toxin–producing Escherichia coli.[3]

Table 69-1

Predisposing Factors, Symptoms, and Therapy of Gastrointestinal Infections

Pathogen	Predisposing Factors	Symptoms	Diagnostic Evaluations	Drug of Choice[a],[c]	Alternatives[a],
Salmonella (non-typhoidal)[b]	Ingestion of contaminated poultry, raw milk, custards, and cream fillings; foreign travel	Nausea, vomiting, diarrhea, cramps, fever, tenesmus.Incubation: 6–72 hours	Fecal leukocytes, stool culture	Fluoroquinolone, azithromycin, third-generation cephalosporins	Amoxicillin, TMP–SMX
Salmonella (typhoidal)	Ingestion of contaminated food; foreign travel	High fever, abdominal pain, headache, dry cough	Fecal leukocytes, stool culture,	Fluoroquinolone, azithromycin, third-generation	TMP–SMX, amoxicillin

			blood culture	cephalosporins	
Shigella	Ingestion of contaminated salad, raw vegetables, swimming in water contaminated with sewage; foreign travel	Fever, dysentery, cramps, tenesmus.Incubation: 24–48 hours	Fecal leukocytes, stool culture	Fluoroquinolone, azithromycin, ceftriaxone	TMP–SMX, ampicillin
Campylobacter	Contaminated eggs, raw milk, or poultry; foreign travel	Mild-to-severe diarrhea; fever, systemic malaise. Incubation: 24–72 hours	Fecal leukocytes, stool culture	Erythromycin, azithromycin	–
Clostridium difficile	Antibiotics, antineoplastics	Mild-to-severe diarrhea, cramps	C. difficile toxin, C. difficile culture, colonoscopy	Metronidazole	Vancomycin
Staphylococcal food poisoning	Custard-filled bakery products, canned food, processed meat, ice cream	Nausea, vomiting, salivation, cramps, diarrhea; usually resolves in 8 hours.Incubation: 2–6 hours	–	Supportive therapy only	–
Travelers' diarrhea (Enterotoxigenic Escherichia coli, Campylobacter)	Contaminated food (vegetables and cheese), water; foreign travel	Nausea, vomiting, mild-to-severe diarrhea, cramps	Stool culture	See Table 69-3	–
Shiga toxin–producing Escherichia coli (E. coli O157:H7)	Beef, raw milk, water	Diarrhea, headache, bloody stoolsIncubation: 48–96 hours	Stool cultures on MacConkey's sorbitol	Supportive therapy only	–
Cryptosporidiosis	Immunosuppression, day-care centers, contaminated water, animal handlers	Mild-to-severe diarrhea (chronic or self-limited); large fluid volume	Stool screening for oocytes, PCR, ELISA	See Chapter 77, Opportunistic Infections in HIV-Infected Patients	–
Viral gastroenteritis	Community-wide outbreaks, contaminated food	Nausea, diarrhea (self-limited), cramps. Incubation: 16–48 hours	Special viral studies	Supportive therapy only	–

ELISA, enzyme-linked immunosorbent assay; PCR, polymerase chain reaction; TMP–SMX, trimethoprim sulfamethoxazole.

This chapter focuses on the diagnosis and management of the common microbial causes of acute infectious diarrhea.

DEFINITIONS

Diarrhea is often defined as three or more episodes of loose stools or any loose stool with blood during a 24-hour period, which may be accompanied by nausea, vomiting, or abdominal cramping.[3] The duration of illness is considered acute if symptoms are present for less than 2 weeks duration, persistent if symptoms last for 14 to 29 days, and chronic if symptoms last ≥30 days.[3] Classifying diarrheal syndromes as either a noninflammatory (watery diarrhea) or an inflammatory (bloody diarrhea) illness provides a basis for predicting the most likely microbial cause for the intestinal illness.[1]

PATHOGENESIS

The pathogenesis of infectious diarrhea involves an interplay among bacterial virulence factors, host factors, and predisposing factors to infection. Diarrhea is more likely to occur in the setting in which an imbalance among these factors favors the enteropathogen.

Bacterial Virulence Factors

Enteropathogens possess virulence factors that contribute to the organism's pathogenicity.[2] Enterotoxins targeting the small bowel cause net movement of fluid into the gut lumen, leading to voluminous watery stools and potentially life-threatening dehydration. Cytotoxins targeting the colon cause direct mucosal damage, leading to fever and bloody diarrhea. Invasive properties of Shigella species and invasive strains of E. coli allow these bacteria to invade and destroy epithelial cells, causing bloody or mucoid stools. Some enteropathogens induce a vigorous host response through the release of proinflammatory cytokines from intestinal epithelial cells, leading to diarrhea. Finally, adhesions allow enteropathogens to attach to and colonize the gastrointestinal (GI) mucosa, facilitating toxin delivery, invasion, dissemination, or host cell lysis.[2]

Host Defenses

The human GI tract possesses numerous defense mechanisms to protect against enteric infection. Normal bacterial flora compete for space and nutrients with potentially pathogenic organisms, or produce substances, e.g., short-chain fatty acids, that are inhibitory to enteropathogens.[2] Gastric acidity of the stomach prevents acid-susceptible pathogens from passing from the stomach into the intestinal tract, whereas gastrointestinal mucus and mucosal tissue integrity provide physical barriers against infection. Intestinal immunity includes defensins that are bactericidal to some enteropathogens, local production of antibodies, and toll-like receptors that recognize enteropathogens and activate the immune response.[2] Intestinal peristalsis moves bacteria and their toxins along and out of the GI tract. Finally, specific host genetic factors are protective against enteric infection.[3]

Predisposing Factors

Inadequate sanitation facilities increase the risk that local inhabitants and travelers will be exposed to contaminated food and water. Outbreaks of foodborne or waterborne illnesses in both industrialized and developing countries facilitate the spread of infectious organisms. Industrialized countries that rely on imported food items risk the possibility of importation of contaminated food products.[4] Immunocompromised hosts, such as organ transplant recipients and patients receiving immunosuppressive therapies, are more susceptible to intestinal infection. Institutional settings such as day-care centers, hospitals, and extended-care facilities are high-risk settings for dissemination of disease. Finally, poor personal hygiene is a risk for infectious diarrhea.

Table 69-2

Pharmacologic Agents that May Promote Gastrointestinal Infection

Drug	Mechanism
Antacids, H_2-receptor antagonists, proton-pump inhibitors	Increase of gastric pH; passage of viable pathogens to lower gut
Antibiotics	Alteration of intestinal flora
Cancer chemotherapy	Unclear but may include the antimicrobial activity of chemotherapeutic agents, or chemotherapy-induced intestinal damage and necrosis favoring an anaerobic environment for the growth of C. difficile.

Source: DuPont HL. Acute infectious diarrhea in immunocompetent adults. N Engl J Med. 2014;370:1532; Cohen SH et al. Clinical practice guidelines for Clostridium difficile infection in adults: 2010 update by the Society of Healthcare Epidemiology of America (SHEA) and the Infectious Diseases Society of America (IDSA). Infect Control Hosp Epidemiol. 2010;31:431; Anand A, Glatt AE. Clostridium difficile infection associated with antineoplastic chemotherapy: a review. Clin Infect Dis. 1993;17:109.

The use of pharmacologic agents, e.g., drugs that increase gastric pH (Table 69-2), increases the risk for infection with acid-susceptible pathogens such as Salmonella species and Vibrio cholerae.[5] The use of proton-pump inhibitors predisposes patients to Clostridium difficile diarrhea.

MANAGEMENT OVERVIEW

Rehydration Therapy

The most common complication of any diarrheal illness is loss of fluids and electrolytes, which in extreme cases can lead to hypovolemia, shock, and death.[1] Depending on the degree of dehydration, fluid and electrolyte losses are replaced intravenously (IV) or orally. Once replacement of fluid and electrolyte losses is completed, additional laboratory tests and drug therapies can be considered.

Laboratory Tests

Inflammatory diarrheal illnesses are characterized by the presence of bloody or mucoid stools. Therefore, stool specimens with red blood cells (RBCs) or occult blood, or those that contain large numbers of white blood cells, suggest infection attributable to invasive pathogens.[6]

Identification of bacterial toxins in stool specimens is a useful diagnostic tool. For example, because only the toxigenic strains of C. difficile are pathogenic, the presence or absence of bacterial toxins in stool specimens is more important than a positive culture for the organism.[7]

In clinical practice, routine microbiologic identification of pathogens utilizes selective media which favors the growth of suspected pathogens.[7] Stool cultures are recommended for patients with one of the following: acute diarrhea that is severe or associated with a temperature >38.5°C; dysentery—which is an inflammatory diarrheal illness characterized by bloody or mucoid stools with abdominal cramps; profuse cholera-like watery diarrhea; dehydration; elderly or immunocompromised patients; nursing home patients; food handlers; and day-care workers.[3] Hospitalized patients should be evaluated for C. difficile infection. Culture of specimens from extraintestinal sites of infection (e.g., blood cultures) can be used to identify the microbial etiology.

PCR-based diagnostic tests are widely available in industrialized countries, offering improved sensitivity but focusing on genes versus virulence factors.[3]

Drug Therapy

Drug therapy for infectious diarrhea includes medications to provide symptomatic relief or to eradicate the causative pathogen.

LOPERAMIDE AND DIPHENOXYLATE/ATROPINE

Loperamide and diphenoxylate/atropine reduce the frequency of diarrheal stools by slowing intestinal transit time; additionally, loperamide possesses antisecretory properties.[8] Loperamide is preferred over diphenoxylate/atropine because of its greater efficacy, better tolerance, and over-the-counter availability. Diphenoxylate/atropine causes drowsiness, dizziness, dry mouth, and urinary retention owing to the atropine component, and its use in the elderly is not recommended (see Chapter 107 Geriatric Drug Use).

The use of antimotility drugs is not recommended in persons with fever, bloody diarrhea,[3] or when invasive pathogens are suspected.[1] The primary concern is that prolongation of clearance of pathogens from the intestinal tract could worsen the severity of illness. However, in non-critically ill patients with bacillary dysentery, loperamide was not harmful when administered with antimicrobials to which the infecting pathogen was susceptible.[9]

BISMUTH SUBSALICYLATE (BSS)

Bismuth subsalicylate’s antidiarrheal properties are because of its antisecretory, adsorbent, and antimicrobial properties.[10] Problems with BSS include the inconvenience of dosing 4 times per day, and adverse effects such as darkening of the tongue and stools, and tinnitus secondary to salicylate absorption. Each recommended antidiarrheal dose of BSS of 526 mg contains 263 mg of salicylate, and this needs to be considered in patients already taking salicylate products.

CROFELEMER

Crofelemer is a recently U.S. Food and Drug Administration (FDA)–approved non-absorbable agent indicated for the symptomatic treatment of noninfectious diarrhea in HIV-infected persons on antiretroviral therapy. [11] Its antisecretory effect is because of the unique inhibition of two distinct channels responsible for chloride and fluid secretion into the GI tract. Crofelemer improves diarrheal symptoms in patients with noninfectious diarrhea; larger trials are needed to further assess its efficacy and safety in patients with infectious diarrhea. Common side effects of cofelemer include flatulence (7%) and abdominal pain (5%).[11]

PROBIOTICS

Interest in probiotics stems, in part, from their potential to decrease the use of antibiotics. These live microbial mixtures of bacteria and yeasts are used to restore the normal intestinal flora, thereby reducing intestinal colonization with pathogenic organisms. Probiotics also produce pathogen-inhibiting substances, prevent pathogen adhesion to the GI tract, inhibit the action of microbial toxins, and stimulate immune defense mechanisms.[12] Further studies are needed to clarify the role of specific probiotics for the treatment and prevention of acute infectious diarrhea.[12],[13]

ANTIMICROBIALS

In selected cases, antimicrobials are prescribed to decrease the duration and the severity of diarrheal illnesses, to prevent the progression to invasive infection, and prevent person-to-person transmission of pathogens. Antimicrobials are generally recommended for the severely ill, for patients with conditions compromising normal enteric defenses, for immunocompromised patients, and for the treatment of extraintestinal infection.[3]

Ongoing surveillance of antimicrobial resistance is important to guide treatment recommendations. Extensively used in the past and resulting in widespread resistance to common enteropathogens, trimethoprim–sulfamethoxazole (TMP–SMX), the aminopenicillins, nalidixic acid, and tetracyclines are unsuitable empiric choices for the treatment of many enteropathogens. Depending on the circumstances surrounding the diarrheal illness, including where the pathogen was acquired (e.g., domestic vs. travel-related), age, and allergy history of the patient, commonly recommended antimicrobials include selected third-generation cephalosporins (e.g., ceftriaxone or cefotaxime), azithromycin, rifaximin, fluoroquinolones, and others.[3]

The fluoroquinolones, although still recommended because of their efficacy against susceptible organisms[3] and their availability as oral formulations, must be used cautiously as common enteropathogens, e.g., Shigella, Salmonella, and Campylobacter species, are frequently fluoroquinolone-resistant.[14] Another consideration with using fluoroquinolones is that they are not FDA-approved for use in children because lesions on cartilage tissue have been reported in juvenile animals. Nevertheless, because of the emergence of multidrug-resistant enteropathogens in some geographic areas, clinical trials using fluoroquinolones in children have been performed,[15] and the available data suggest that a short course of these agents is safe. Finally, antimicrobial use should be limited to instances where their benefits outweigh their risks for adverse effects and resistance.

Prevention

Good personal hygiene along with proper food handling, cooking, and storage are essential to prevent the spread of enteropathogens. When visiting areas with inadequate facilities for the disposal of sewage, travelers should follow the rule, “boil it, cook it, peel it, or forget it.” Effective vaccines are available to prevent typhoid fever, rotavirus, and cholera (not available in the United States); studies of vaccines to prevent Campylobacter, enterotoxigenic E. coli, and Shigella infections are ongoing.[1]

EVALUATION AND TREATMENT OF PATIENTS WITH INFECTIOUS DIARRHEA

CASE 69-1

QUESTION 1: B.K. is a 78-year-old man presenting to his physician with a diarrheal illness for 1 day. His illness began with vomiting and was followed by abdominal pain, nausea, and watery, but non-bloody, diarrhea. Despite not feeling well, he is able to drink fruit juices. B.K.'s history of present illness is significant for eating raw oysters at a local seafood restaurant 2 days ago, and he has since learned that other patrons are experiencing a similar illness. B.K. has no significant medical history. He denies recent hospitalization, contact with small children, recent travel, or recent use of antimicrobials. On physical examination B.K. is alert and oriented, is not "toxic" appearing, afebrile, and has stable vital signs. The remainder of his examination is significant for decreased skin turgor and dry mucous membranes. What is your general approach to the management of B.K.'s diarrheal illness?

Because infectious diarrhea is typically a self-limiting illness, patients may never seek medical attention, and in many cases, replacement of fluids and electrolytes is all that is required. In general, medical evaluation is warranted for patients with profuse watery diarrhea with dehydration, bloody stools, temperature greater than 101.3°F, or illness of more than 48 hours duration. Other persons requiring medical evaluation include patients older than 50 years of age with severe abdominal pain and immunocompromised patients (e.g., those with acquired immunodeficiency syndrome, organ transplant recipients, or patients being treated with cancer chemotherapies). Noninfectious causes for the illness such as medications, inflammatory bowel disease, consumption of poorly absorbable carbohydrates (e.g., sugarless candies or chewing gum), or malabsorption syndromes should be considered.[6]

CASE 69-1, QUESTION 2: What rehydration plan would you recommend for B.K.?

B.K.'s physical examination is significant for decreased skin turgor and dry mucous membranes, findings consistent with mild-to-moderate volume depletion.[16] Given that B.K. is not "toxic" appearing, with stable vital signs, and is tolerating oral liquids, oral beverages containing glucose (e.g., lemonades, sweet sodas, or fruit juices) or soups rich in electrolytes are appropriate.[17] In developing countries, significant reductions in dehydration-related mortality is attributed to oral replacement therapy solutions containing optimal concentrations of sodium, potassium, chloride, bicarbonate, and glucose; the glucose content of these solutions is responsible for accelerating the absorption of sodium.[5]

Intravenous replacement therapy is warranted for severe dehydration—characterized by lethargy, very sunken and dry eyes, a very dry tongue and mouth, a pulse that is fast, weak or non-palpable, poor urine output, and low blood pressure—or for persons with intestinal ileus or who are unable to drink on their own.[16]

CLINICAL PRESENTATION

CASE 69-1, QUESTION 3: How does B.K.'s clinical presentation as a noninflammatory versus inflammatory diarrheal illness help to guide further treatment?

The clinical presentation (e.g., the specific symptoms, the severity and duration of symptoms), along with the history of present illness (e.g., risk factors for infection), allows for classification of diarrheal syndromes as noninflammatory versus inflammatory illnesses. Such a classification allows the physician to consider a more focused list of potential enteropathogen(s), and based on the list of suspected organisms, a diagnostic and therapeutic plan can be developed.[7]

B.K.'s history of present illness and clinical presentation are consistent with a noninflammatory diarrheal illness. Voluminous, watery, non-bloody diarrhea is characteristic of pathogens targeting the small bowel, which is responsible for absorption of most fluids entering the GI tract.[7] The clinical manifestations of noninflammatory, watery diarrheal illnesses are a consequence of bacterial enterotoxins that promote the secretion of water and electrolytes into the intestinal lumen; or of viruses infecting and damaging the absorptive villus tips, resulting in voluminous watery diarrhea.[7] Like B.K., patients with noninflammatory diarrheal illnesses are not severely ill, are afebrile and without significant abdominal pain[2],[7]; most patients require only supportive therapies. Noninflammatory diarrheas are typically caused by viruses (e.g., rotaviruses and noroviruses), bacteria (e.g., Staphylococcus aureus, Bacillus cereus, and Clostridium perfringens), or parasites (e.g., Cryptosporidium parvum and Giardia lamblia).[1]

In contrast, inflammatory diarrheas are generally a more severe illness characterized by diarrhea with or without dysentery, abdominal pain, and fever.[2] Pathogens targeting the distal small bowel and colon disrupt the epithelial barrier, causing the bloody or mucoid stools.[2] In addition to supportive therapies, selected persons with inflammatory diarrheal illnesses may benefit from antimicrobial therapy directed at the causative pathogen. The clinical manifestations of inflammatory diarrheal illnesses are a consequence of the production of cytotoxins (e.g., as produced by C. difficile, Shiga toxin–producing E. coli, and enteroaggregative E.

coli), or of the pathogen's ability to invade the intestinal mucosa (e.g., Campylobacter jejuni, Shigella species, and Salmonella species).[18]

VIRAL GASTROENTERITIS

Clinical Presentation and Treatment

CASE 69-1, QUESTION 4: B.K.'s stool is negative for WBCs and RBCs. With B.K.'s history of dining at the same restaurant as other patrons having a similar illness, the physician calls the Board of Health to find out if similar illnesses are being reported throughout the city. The physician is informed that an outbreak of norovirus (previously called Norwalk-like virus) gastroenteritis was confirmed at the restaurant where B.K. had dined. Why is B.K.'s history of present illness and clinical presentation consistent with the presumptive diagnosis of a viral gastroenteritis, specifically the norovirus? What supportive therapies are recommended?

Noroviruses are responsible for major outbreaks of foodborne viral illnesses in both adults and children, usually in association with restaurants, schools, and day-care centers. The virus is spread by eating inadequately cooked clams and oysters harvested from contaminated waters and other contaminated foods (e.g. salads, sandwiches), by person-to-person contact, or by exposure to contaminated recreational waters. Like B.K., within 12 to 48 hours after exposure to the virus, patients complain of nausea, vomiting, diarrhea, and abdominal cramps. B.K. will likely experience a mild intestinal illness lasting 1 to 3 days. Supportive therapies to correct fluid and electrolyte losses and to replace ongoing losses are the mainstay of treatment for viral gastroenteritis. Preventing future outbreaks will require the restaurant to ensure proper food-handling practices.[19]

Other common causes of viral gastroenteritis are rotaviruses and astroviruses which are responsible for 30% to 60% of all cases of severe, watery diarrhea in children. After an incubation period of 1 to 3 days, patients experience fever, vomiting, and non-bloody, watery diarrhea; otherwise healthy persons are typically ill for 5 to 7 days.

In the United States, two oral rotavirus vaccines are available for the prevention of rotavirus gastroenteritis in infants and children, a pentavalent (three-dose series) and a monovalent

---

(two-dose series). Vaccine effectiveness in high and upper middle income countries ranges from 79% to 100%, with the benefit of vaccination outweighing vaccine risks, e.g., intussusception (when a part of the intestine folds into another adjacent part of the intestine, referred to as "telescoping," which can lead to intestinal obstruction).[20] As rotaviruses are spread by the fecal–oral route, proper hand washing and disposal of contaminated items are essential to limit the spread of infection.

VIBRIO SPECIES

Vibrio species are curved gram-negative rods whose natural habitats are the environmental waters throughout the world. V. cholerae 01 and 0139 are noninvasive enteropathogens responsible for epidemic cholera in humans. The ongoing seventh cholera pandemic began in 1961, subsequently spreading through Asia to Africa, Europe, and Latin America.[5] Prevention of cholera relies on the provision of safe drinking water and adequate sanitation. Cholera vaccines are not routinely incorporated into cholera control efforts, in part related to financial and logistical reasons.[5] Non-cholera Vibrio species (e.g., Vibrio parahaemolyticus) do not possess the virulence factors required to cause epidemic cholera but do cause gastroenteritis, wound infections, and in susceptible hosts, fulminant sepsis.[21]

Vibrio Cholerae

RISK FACTORS AND CLINICAL PRESENTATION

CASE 69-2

QUESTION 1: M.M. is a 50-year-old man hospitalized for severe watery diarrhea, vomiting, muscle cramping with weakness, and confusion, notably unable to recognize his family members. His history of present illness is significant for returning 1 day ago from Haiti where he visited with relatives, several of whom were recovering from diarrheal illnesses caused by V. cholerae. Approximately 24 hours before admission, he noted the onset of watery diarrhea and immediately began drinking the oral rehydrating solution remaining from his trip to Haiti. However, over the past several hours he has been unable to drink on his own, and his family noticed “white flecks” in his stools. M.M. lives in Florida, and his past medical history is significant for peptic ulcer disease for which he takes a proton-pump inhibitor.

In the emergency department, M.M.’s vital signs are as follows: afebrile, blood pressure is 70/40 mm Hg, and heart rate is 130 beats/minute. Physical examination reveals a severely ill-appearing man with altered mental status, sunken eyes, poor skin turgor, and dry mucous membranes. The physician’s assessment is severe dehydration because of massive diarrhea, most likely caused by V. cholerae. What are his risk factors for cholera and why is his clinical presentation consistent with this diagnosis?

Risk Factors

M.M. has two risk factors to explain his presumed diagnosis of cholera. First, he has just returned from Haiti, a county suffering from epidemic cholera following a major earthquake in 2010 that severely damaged public health facilities.[5] In developed countries, cholera has been virtually eliminated because of modern sewage and water treatment systems. However, sporadic cases, like M.M., occur in travelers returning from areas where cholera is epidemic or endemic, or from the consumption of contaminated and undercooked seafood (e.g., improperly preserved fish, raw oysters, and shellfish) from waters off the Gulf Coast States or imported from endemic areas.[22] Second, M.M.'s daily use of a proton-pump inhibitor reduces his stomach's acidity, thus allowing the acid-susceptible V. cholerae to pass from the stomach into the small intestine.[5]

Clinical Presentation

Cholera epidemics are caused by toxin-producing strains of V. cholerae 01 or 0139.[5] The characteristic voluminous, watery, and colorless stools with "white flecks" of mucus (referred to as rice-water stools because of their similarity to the appearance of water after washing rice) are caused by the cholera toxin which promotes the intestinal secretion of fluids and electrolytes.[5]

The severity of cholera and likelihood of infection is influenced by host factors and the setting in which it occurs.[5] Severe disease is more common in previously unexposed persons like M.M. who are immunologically naïve (e.g. epidemic cholera), while less severe disease occurs in areas where cholera is endemic.[5] Following ingestion of contaminated foods, a watery diarrheal illness begins within 12 hours to 5 days and may progress to life-threatening dehydration.[5]

TREATMENT

CASE 69-2, QUESTION 2: What are the signs and symptoms suggesting M.M. is severely dehydrated, and how should his dehydration be treated?

M.M. is one of the 2% to 5% of persons with V. cholerae infection who experience severe dehydration (≥10% dehydration), losing up to 1 L/hour of fluid, and whose condition may, within hours, progress to hypovolemic shock and death.[5] M.M. shows signs of severe dehydration as manifested by his altered mental status, sunken eyes, poor skin turgor, dry mucous membranes, low blood pressure, and increased heart rate.[5] Acidosis may occur as a result of massive bicarbonate losses through diarrheal stools, and it may be exacerbated by lactic acidosis from shock and hypovolemic renal failure.[5] M.M. should receive vigorous IV hydration with Ringer's lactate solution to replace the large quantities of sodium, potassium, and bicarbonate lost through his watery stools; his muscle weakness could be attributed to depletion of electrolytes, specifically potassium and calcium.[5] Monitoring of blood pressure and normalization of heart rate are critical interventions.

Once M.M. is able to drink fluids, oral hydration can be started, even with ongoing IV hydration. Oral replacement solutions containing less than 75 mEq/L of sodium are inappropriate because of the large amounts of sodium lost through cholera stools.[5] Oral rehydration solutions can be made by mixing together one-half teaspoon salt, six teaspoons sugar and 1 liter of safe water.[5]

CASE 69-2, QUESTION 3: Would M.M. benefit from the administration of antimicrobials, and what antimicrobial treatment options are available?

Antimicrobials are recommended for patients with moderate-to-severe dehydration from cholera infection.[5] Effective antimicrobial therapy decreases the volume of diarrheal losses, shortens the duration of illness by up to 50% and reduces the period of shedding infectious organisms from >5 days[23] to 1–2 days.[5] Antimicrobials should be administered after the initial fluid deficit has been corrected and if applicable, after vomiting has resolved.[5]

Antimicrobials

If susceptible, the following single- and multiple-dose regimens are effective treatments for V. cholerae; single-dose regimens are preferred because of their ease of administration, and compared to multiple doses of erythromycin, they are better tolerated.[24]

- Adults: doxycycline 300 mg orally × 1 dose, or azithromycin 1 g orally × 1 dose, ciprofloxacin 500 mg orally twice a day for 3 days,[5] or tetracycline 500 mg orally every 6 hours for 3 days, or erythromycin 250 mg orally 4 times daily for 3 days.[5] TMP–SMX resistance precludes its empiric use for the treatment of cholera.[5]
- Children: ciprofloxacin 15 mg/kg/dose orally twice a day × 3 days, or azithromyc 20 mg/kg orally × 1 dose, or erythromycin 12.5 mg/kg/dose orally every 6 hours for 3 days. Pediatric doses should not exceed maximum adult doses.[5]

For M.M., a single 300 mg oral dose of doxycycline is a good empiric choice as the strain of V. cholerae circulating in Haiti is currently susceptible to tetracycline (indicative of susceptibility to doxycycline).[23] Empiric ciprofloxacin is not recommended because the circulating strain in Haiti has reduced susceptibility to ciprofloxacin which is associated with lack of clinical and microbiologic improvement.[25] Additionally, until M.M. has recovered from this cholera infection, he should refrain from taking his proton-pump inhibitor which, by reducing his stomach's acidity, allows the acid-susceptible V. cholerae to pass from the stomach into the small intestine.

Vibrio Parahaemolyticus

CLINICAL PRESENTATION

CASE 69-3

QUESTION 1: C.T. is a 45-year-old man presenting to his physician with 1 day of non-bloody, watery diarrhea. Two days before his illness, he ate a meal of raw oysters at a restaurant specializing in fresh local seafood. C.T. lives along the coast of Florida and has no significant medical history. His physical examination reveals no evidence of dehydration. Why is C.T.'s history of present illness and clinical presentation consistent with non-cholera Vibrio gastroenteritis?

A key piece of information from C.T.'s history of present illness consistent with the presumptive diagnosis of non-cholera Vibrio gastroenteritis is consumption of raw oysters harvested from the coastal areas of Florida, where V. parahaemolyticus species have been identified. Diarrhea, abdominal cramps, nausea, vomiting, and fever begin after a median incubation period of 17 hours (range, 4–90 hours); bloody diarrhea occurs in 9% to 29% of cases.

TREATMENT

CASE 69-3, QUESTION 2: Should a course of antibiotics be prescribed for C.T.?

In otherwise healthy adults like C.T., V. parahaemolyticus gastroenteritis is usually a mild, self-limiting illness lasting for a median of 2 to 6 days.[21] There are no data to support the benefit of antibiotics in this setting, although patients with diarrhea lasting longer than 5 days may benefit from treatment with tetracycline or a fluoroquinolone; minocycline 100 mg orally every 12 hours and cefotaxime 2 g IV every 8 hours have also been recommended.[21]

Individuals with liver disease or alcoholism are at risk for severe Vibrio infections including septicemia[21]; such individuals should avoid eating raw or undercooked shellfish, and avoid exposure of open wounds to seawater especially during the warmer months when water temperatures favor the growth of Vibrio species.

STAPHYLOCOCCUS AUREUS, BACILLUS CEREUS, AND CLOSTRIDIUM PERFRINGENS

S. aureus, B. cereus, and C. perfringens are important causes of toxin-mediated foodborne illnesses. Gastrointestinal symptoms typically begin within 24 hours after the ingestion of contaminated foods, which is in contrast to the longer incubation periods for illnesses caused by Salmonella, Shigella, and Campylobacter species. B. cereus causes two different intestinal syndromes: the short-incubation disease characterized by vomiting and a long-incubation disease characterized by a diarrheal illness.[1]

Clinical Presentation and Treatment

CASE 69-4

QUESTION 1: S.A. is an otherwise healthy 23-year-old college student, who presents to the Student Health Center with an acute gastrointestinal illness after eating at the school cafeteria. S.A. recalled eating the salad and the cream-filled pastries, and stated that within 3 hours she felt nauseous and began vomiting. Why is S.A.'s history of present illness and clinical presentation consistent with food poisoning caused by S. aureus or B. cereus (short-incubation)?

Foodborne illnesses are often grouped by their usual incubation period: less than 6 hours, 8 to 16 hours, and greater than 16 hours.[26] The rapid onset (within 6 hours) of S.A.'s intestinal symptoms after eating suggests the illness is caused by preformed toxins, such as those produced by S. aureus or B. cereus (short-incubation disease, emetic syndrome). Diarrhea and abdominal cramps may also occur. Although cooking kills the toxin-producing bacteria, it does not destroy toxin that has already been produced. Foods implicated in staphylococcal food poisoning include salads, cream-filled pastries, and meats, whereas foods implicated in B. cereus food poisoning include fried rice, dried foods, and dairy products.[26]

CASE 69-5

QUESTION 1: C.P. is also an otherwise healthy 23-year-old college student presenting to the same Student Health Center as S.A. (Case 69-4) with an acute gastrointestinal illness. C.P. recalled having lunch at the cafeteria, selecting a fish and poultry meal. Approximately 10 hours after eating she experienced diarrhea and abdominal cramps. Why is C.P.'s history of present illness and clinical presentation consistent with food poisoning caused by C. perfringens or B. cereus (long-incubation disease)? Should empiric antibiotics be prescribed to either of these students?

In contrast to S.A., the longer incubation period before the onset of symptoms is consistent with illness caused by C. perfringens or B. cereus (long-incubation disease, diarrheal syndrome). These bacteria are associated with an incubation period of 8 to 16 hours and symptoms of diarrhea and abdominal cramps; vomiting is not a prominent symptom in these illnesses.[26]

C. perfringens or B. cereus (long-incubation disease) produce heat-labile toxins after the ingestion of contaminated foods, explaining the longer incubation period compared with illness caused by the ingestion of preformed toxins. Foods implicated in C. perfringens food poisoning include improperly stored beef, fish, poultry dishes, pasta salads, and dairy products, whereas foods implicated in long-incubation B. cereus food poisoning include meats, vanilla sauce, cream-filled baked goods, and salads.[26]

Foodborne illnesses caused by these toxin-producing bacteria usually resolve within 24 hours; therefore, antibiotic therapy is not indicated for either student.

CRYPTOSPORIDIUM PARVUM

The protozoan parasite C. parvum is an important cause of human intestinal illness in both healthy and immunocompromised persons. The role of antiprotozoal agents and the clinical response to antiprotozoal therapy depends on the competence of the host's immune system.

Clinical Presentation

CASE 69-6

QUESTION 1: C.K. is a 35-year-old, previously healthy man presenting to his physician with complaints of 15 days of watery diarrhea and a 5-pound weight loss. He is concerned that his illness is related to the announcement by the Board of Health notifying the community of an outbreak of cryptosporidiosis from contaminated water supplies. Why is C.K.'s history of present illness and clinical presentation consistent with cryptosporidiosis? Should antiprotozoal agents be prescribed to treat cryptosporidiosis in otherwise healthy persons such as C.K.?

A key finding from C.K.'s history is his exposure to water supplies known to be contaminated with cryptosporidium oocysts; other modes of spreading cryptosporidiosis include animal contact (cattle and sheep) and person-to-person contact.[27]

C.K. is presenting with persistent diarrhea, i.e., diarrhea lasting longer than 14 days. Common microbial causes of persistent watery diarrhea include parasites, such as Isospora belli, Microsporidia, G. lamblia, and C. parvum. The spectrum of infection with C. parvum ranges from asymptomatic carriage to a persistent, noninflammatory diarrheal illness; vomiting, abdominal cramps, weight loss, and fever may also occur.[27] Immunocompetent patients like C.K. can generally expect a self-limiting illness lasting approximately 2 weeks.[27]

In contrast, in immunocompromised patients cryptosporidiosis can be a chronic, debilitating, diarrheal illness associated with malnutrition, increased mortality, and in children, long-term cognitive impairment.[28]

Treatment

For immunocompetent hosts with cryptosporidiosis, other than replacement of fluids and electrolytes no specific therapy directed at the organism is generally required. However, nitazoxanide is an FDA-approved treatment for diarrhea caused by C. parvum. A randomized, double-blind, placebo-controlled trial in immunocompetent adults and children found that diarrhea resolved in 80% of those treated with nitazoxanide versus 41% of patients given placebo; oocyst shedding was also significantly reduced in the treatment group. Diarrhea generally resolved within 3 to 4 days of starting treatment.[29] Nitazoxanide 500 mg orally twice daily for 3 to 14 days is recommended for the treatment of cryptosporidiosis.[3]

In contrast, in immunocompromised persons a meta-analysis of treatments for cryptosporidiosis found no evidence to support the role of chemotherapy.[30] These findings are consistent with randomized trials concluding that neither a short, 3-day course of nitazoxanide nor a more intensive regimen of nitazoxanide (200–400 mg orally twice daily for 28 days) provided any benefit to HIV-positive children. For HIV-infected persons, reconstitution of the immune system with effective antiretroviral therapies is the mainstay of treatment for cryptosporidiosis.

SALMONELLA

Salmonellae are enteric gram-negative bacilli belonging to the Enterobacteriacae family. Widely found in nature colonizing animal hosts including mammals, reptiles, and birds,[31] they are major causes of foodborne illness as a consequence of consuming contaminated foods including poultry or poultry products and dairy products. Worldwide, the annual incidence of salmonellosis is about 1.3 billion cases, and of the nearly 3 million persons who die,[32] most live in developing areas of the world.

The role of antimicrobials in the management of salmonellosis depends on the clinical syndrome, its severity, and underlying health problems of infected persons. Non-typhoidal salmonellae (e.g., Salmonella typhimurium, Salmonella enteritidis, Salmonella choleraesuis, and many others) cause the clinical syndromes of gastroenteritis, asymptomatic carriage in the stool, bacteremia, and localized infection.[33] Typhoidal salmonellae (Salmonella typhi and Salmonella paratyphi A, B, and C) cause the syndromes of enteric fever (also referred to as typhoid or paratyphoid fever) and chronic carriage.[31]

Non-typhoidal Salmonellosis

CASE 69-7

QUESTION 1: An outbreak of Salmonella gastroenteritis being investigated by the Department of Public Health has traced the source of the outbreak to Restaurant A, specifically the popular turkey dinner special. Anticipating that infected diners with specific clinical syndromes associated with Salmonella infection will benefit from antimicrobial treatment, and that antimicrobial resistant Salmonella species are increasingly problematic, the Department of Health has asked you to address the following question of what antimicrobials are available for the treatment of non-typhoidal salmonellosis.

CHLORAMPHENICOL, TRIMETHOPRIM–SULFAMETHOXAZOLE (TMP–SMX), OR AMPICILLIN

Until the late 1980s, standard treatments for non-typhoidal Salmonella were chloramphenicol, TMP/SMX, or ampicillin. By the early 1990s, widespread multidrug-resistance (MDR) defined as simultaneous resistance to ampicillin, chloramphenicol, streptomycin, tetracyclines, and sulfonamides precluded their use as empiric therapies for the treatment of salmonellosis.[31] Depending on the geographic area, rates of MDR Salmonella species are as high as 80% in East Asia and southern Europe and 30% to 40% in the United States.[32] As MDR-resistant Salmonella species remained susceptible to the fluoroquinolones, these antimicrobials became the agents of choice for the treatment of salmonellosis. Interestingly, since the early 2000s there has been a decline in the prevalence of MDR-non-typhoidal Salmonella in some areas of the world.[32]

FLUOROQUINOLONES

With the advent of MDR-non-typhoidal Salmonella, fluoroquinolones were widely prescribed for the empiric treatment of non-typhoidal salmonellosis.[31] During the 1990s, suboptimal clinical responses following treatment with fluoroquinolones were noted when isolates were resistant to nalidixic acid. Both nalidixic acid and the fluoroquinolones are related compounds belonging to the quinolone family of antimicrobials. As these isolates also displayed elevated ciprofloxacin MICs compared to

---

nalidixic acid–susceptible strains (i.e., 0.12–1 mcg/mL vs. ≤0.06 mcg/mL), they were referred to as having decreased ciprofloxacin susceptibility (DCS).[34] Consequently, nalidixic acid resistance became a surrogate marker for isolates with DCS, for which ciprofloxacin was not an optimal antimicrobial choice.

In subsequent years, additional fluoroquinolone-resistance mechanisms in Salmonella species emerged which were not detected by nalidixic acid screening (i.e., isolates were nalidixic acid susceptible but had elevated ciprofloxacin MICs); thus, nalidixic acid resistance was no longer a reliable surrogate marker to detect Salmonella with DCS.[34] Consequently, in 2012 the Clinical Laboratory Standards Institute (CLSI) lowered for Salmonella species the breakpoint for susceptibility to ciprofloxacin from <1 to <0.06 mcg/mL, a change which would reliably detect Salmonella with DCS. The CLSI also recognized that not all laboratories (e.g., resource-limited settings) would be able to institute these new ciprofloxacin breakpoints, and because nalidixic acid–susceptible isolates with concurrent decreased susceptibility to ciprofloxacin are still uncommon, CLSI allowed for the continued use of nalidixic acid screening,[34] though prescribers should be made aware of its limitations as a marker for isolates with DCS.

Currently, nalidixic acid–resistant non-typhoidal Salmonella are prevalent in Asia and increasingly more common in the United States, reportedly 0.4% in 1996 and

2.3% in 2003. Antimicrobial treatment options for nalidixic acid–resistant Salmonella include azithromycin and selected third-generation cephalosporins.[34]

β-LACTAMS

Non-typhoidal salmonella resistance to ceftriaxone is currently uncommon, but it has been reported worldwide, including in Africa, Europe, Asia, the Philippines, and the United States[31]; some isolates are also simultaneously resistant to fluoroquinolones.[32],[35] Carbapenems[35] have been successfully used for the treatment of invasive infection caused by ceftriaxone- and ciprofloxacin-resistant Salmonella enterica serotype choleraesuis,[36] though carbapenem-resistant Salmonella have also been reported.[31]

AZITHROMYCIN

Azithromycin displays good in vitro activity against non-typhoidal S. enterica[37] and is a recommended treatment for non-typhoidal salmonellosis requiring antimicrobial treatment,[3] including the treatment of nalidixic acid–resistant isolates.

Anticipating the need for recommendations to guide prescribers regarding which diners with salmonellosis should receive antimicrobial therapy, the Department of Health has asked you to address the following question: “Considering a diner’s severity of illness and underlying health problems, should antimicrobials be prescribed for diners with the following clinical syndromes: (a) uncomplicated gastroenteritis in the immunocompetent host, (b) asymptomatic stool carriage, or (c) extraintestinal Salmonella infection? If appropriate, what specific antimicrobial therapies would you recommend?”

UNCOMPLICATED GASTROENTERITIS IN THE IMMUNOCOMPETENT HOST

Clinical Presentation and Treatment

CASE 69-8

QUESTION 1: B.B., a 35-year-old, otherwise healthy man presents with a 1-day history of fever, abdominal pain, nausea, vomiting, and non-bloody stools. B.B. has no significant medical history. Physical examination is significant for a non-ill appearing, febrile male; his presumptive diagnosis is mild, uncomplicated non-typhoidal Salmonella gastroenteritis. Should he receive antimicrobial therapy?

Like B.B., within 6 to 72 hours of ingesting contaminated foods patients begin experiencing the clinical manifestations of Salmonella gastroenteritis including acute onset of fever, diarrhea, and abdominal cramping; in more severe illness, bloody diarrhea and dehydration may occur.

In otherwise healthy individuals with uncomplicated non- typhoidal Salmonella gastroenteritis, antimicrobials are not recommended as salmonellosis is typically a self-limiting illness lasting for 2 to 5 days. Antimicrobials do not reduce the duration or severity of illness and may be harmful, by placing patients at risk for adverse drug reactions, prolonging the asymptomatic carriage of salmonellae, and promoting the emergence of antimicrobial-resistant bacteria.[33],[38] Most individuals like B.B. will only require replacement of lost fluids and electrolytes.

ASYMPTOMATIC STOOL CARRIAGE

Clinical Presentation and Treatment

CASE 69-8, QUESTION 2: Three weeks after resolution of B.B.'s episode of Salmonella gastroenteritis, he continues to excrete Salmonella bacteria from his stool, despite remaining asymptomatic. Should antimicrobials be prescribed to eliminate B.B.'s intestinal carriage of non-typhoidal Salmonella?

Antimicrobials should not be prescribed to eliminate asymptomatic intestinal carriage of non-typhoidal Salmonella.[18] A randomized, double-blind trial in healthy, asymptomatic adults from areas where non-typhoidal Salmonella infection is endemic found that neither norfloxacin nor azithromycin were better than placebo in eradicating intestinal carriage of Salmonella species.[18] The median duration of fecal shedding of non-typhoidal Salmonella is about 1 month in adults and 7 weeks in children younger than 5 years of age.[39]

GASTROENTERITIS IN PATIENTS AT RISK FOR EXTRAINTESTINAL SALMONELLA INFECTION

Clinical Presentation and Treatment

CASE 69-9

QUESTION 1: W.M., a 50-year-old male with a past medical history significant for a recently diagnosed malignancy, presents with a 1-day history of fever, severe abdominal pain, nausea, vomiting, and non-bloody stools. One day prior to the onset of these symptoms, he ate cream-filled pastries from a bakery that has since been closed by the Department of Health because of its association with an ongoing outbreak of Salmonella gastroenteritis. Should antimicrobials be prescribed for his presumed diagnosis of Salmonella gastroenteritis, and if so, what would you recommend?

Antimicrobials are indicated for patients at risk for developing extraintestinal Salmonella infection such as persons with malignancy (like W.M.), diabetes, rheumatologic disorders, HIV infection,[32] persons receiving immunosuppressive therapies, very young age, low gastric pH (e.g., as in infancy, pernicious anemia, or medication-induced), severe infection,[33] and persons older than 50 years of age who may have atherosclerotic lesions which could become hematogenously infected.[40] Overall, less than 5% of patients with non-typhoidal Salmonella gastroenteritis become bacteremic, though infection with some serotypes, e.g., S. choleraesuis and Salmonella dublin are more likely to cause bloodstream infection.[33] Once in the bloodstream extraintestinal complications include osteomyelitis, septic arthritis, meningitis, or infectious endarteritis. Lastly, antimicrobials have been used when rapid interruption of fecal excretion of organisms is needed to control outbreaks of salmonellosis in institutionalized persons.[40]

For patients at risk for extraintestinal infection or with severe diarrhea, antimicrobial options include an oral fluoroquinolone (e.g., levofloxacin 500 mg once daily) for 7 to 10 days, azithromycin 500 mg once daily for 7 days, or parenteral ceftriaxone 1 to 2 grams daily for 7 to 10 days (14 days is recommended for patients with immunosuppression).[3] For HIV-infected persons with a CD4 ≥200 cells/µL, the recommended duration of therapy for gastroenteritis without bacteremia is 7 to 14 days, and for patients with a CD4 <200 cells/µL, 2 to 6 weeks is often recommended.[41]

EXTRAINTESTINAL SALMONELLA INFECTION

Clinical Presentation and Treatment

CASE 69-10

QUESTION 1: B.T., an “ill-appearing” 70-year-old man with a history significant for the same cream-filled pastries as B.T. (Case 659-9, Question 1), who is hospitalized for severe abdominal pain, bloody diarrhea, new-onset right hip pain, high fever, and low blood pressure. His past surgical history is significant for a right hip prosthesis. Would B.T. benefit from antibiotic therapy, and if so, what would you recommend?

B.T. is presenting with signs and symptoms of Salmonella gastroenteritis, bacteremia (fever, low blood pressure) and possible localized infection of his right hip prosthesis (new onset hip pain).

Treatment of Salmonella bacteremia without localized infection is generally successful after 10 to 14 days of antimicrobial therapy.[3],[32] For HIV-infected persons, a longer course of therapy (2–6 weeks) is recommended.[35],[41] If infection of B.T.’s hip prosthesis is confirmed, surgery may be required to cure his infection.[39] Recommended treatment durations for extraintestinal non-typhoidal salmonellosis are available.[40]

Considering the antimicrobial resistance patterns from where the Salmonella infection was acquired (e.g., travel history), prior antimicrobial therapy, and site of infection, until susceptibilities are available empiric therapy options include selected IV third generation cephalosporins (e.g., ceftriaxone 1 g IV q24, cefotaxime 1 g IV q8),[41] an IV or oral fluoroquinolone (e.g., ciprofloxacin 400 mg IV q12h, ciprofloxacin 500–750 mg PO q12h, levofloxacin 750 mg IV or PO q24h), or the combination of a third-generation cephalosporin with a fluoroquinolone.[40] For bacteremic patients, some experts prefer the IV route of administration,[40] particularly until the patient has stabilized,[32] while other experts recommend either the IV or oral route of administration.[41]

Typhoidal Salmonellosis—Typhoid Fever (Enteric Fever)

CLINICAL PRESENTATION

CASE 69-11

QUESTION 1: B.C. is a 49-year-old obese woman, presenting to the emergency department with a 1-week history of fever, confusion and delirium, severe abdominal pain, headache, anorexia, and diarrhea and, for the past 1 day, a red rash on her chest. Her history of present illness is significant for returning 10 days ago from travel to the Indian subcontinent where she stayed with relatives, some of whom were recovering from typhoid fever. B.C.'s medical history is significant for gallstones. She lives in California with her husband. Admission vital signs show a temperature of 101°F, a heart rate of 60 beats/minute and a stable blood pressure. Physical examination is significant for a "toxic appearing" female with a red rash on her chest, splenomegaly, and hepatomegaly. Laboratory tests include the following: WBC is $3.0 \times 10^6/\mu L$, liver function tests are mildly elevated, and the results of two sets of blood cultures are pending. B.C. is given the presumptive diagnosis of severe enteric fever and encephalopathy most likely attributable to S. typhi. Why is her history of present illness, clinical presentation, and laboratory results consistent with this diagnosis?

A key piece of information from B.C.'s history of present illness supporting the diagnosis of typhoid fever is her recent travel to the Indian subcontinent where typhoid fever is endemic, and her contact with relatives recovering from this infection. Other developing countries with endemic typhoid fever include Southeast Asia, Africa, and Latin America.[42] In developed countries, enteric fever is a sporadic disease occurring mainly in travelers returning from areas where the disease is endemic; in the United States 85% of cases of typhoid fever are travel-related.[43]

B.C.'s clinical presentation and laboratory findings are classic for enteric fever. During the 7- to 14-day incubation period,[42] salmonellae multiply within macrophages and monocytes, and systemic manifestations of infection appear after the release of bacteria into the bloodstream. Patients usually present with fever, abdominal pain, anorexia, diarrhea or constipation, headache, dry cough, splenomegaly, and hepatomegaly, while severe illness is characterized by concomitant GI bleeding, encephalopathy, and shock. Bacteremia may be followed by localized infection to the liver, spleen, bone marrow, gallbladder, and Peyer's patches of the terminal ileum.[42] Laboratory abnormalities consistent with typhoid fever include B.C.'s low WBC count and mildly elevated liver function tests.[31]

TREATMENT

CASE 69-11, QUESTION 2: Would B.C. benefit from a course of antimicrobials to treat her presumptive diagnosis of typhoid fever? If so, what options are available?

B.C. would benefit from effective antimicrobial treatment for typhoid fever in the following ways: (1) shortening the resolution of fever from 3 to 4 weeks to 3 to 5 days,[44] with clearing of all symptoms within 7 to 10 days,[45] (2) decreasing mortality from usually 5% to 10% to less than 1%,[31] (3) eradicating fecal shedding of S. typhi, thereby limiting further spread of infection,[45] and (4) preventing relapse of infection. Most cases of typhoid fever are effectively treated with oral antimicrobials; IV therapy is reserved for severely ill patients or patients with persistent vomiting and severe diarrhea.[42]

Chloramphenicol, TMP–SMX, or Ampicillin

Until the late 1980s, typhoid fever was cured in more than 90% of patients treated with 14 to 21 days of chloramphenicol, TMP–SMX, or ampicillin.[46] By the early 1990s multidrug-resistant (i.e., simultaneous resistance to chloramphenicol, ampicillin, and TMP-SMX) S. typhi caused outbreaks of typhoid fever in Asia and Africa. Fortunately, these multidrug-resistant isolates remained susceptible to the fluoroquinolones, which then became the antimicrobials of choice. Interestingly, there has been a reduction in multidrug- resistant S. typhi to as low as 12% in some areas of the world.

Fluoroquinolones

Short-treatment courses (less than 5 days) of oral fluoroquinolones were once as effective or better than previously used treatments (e.g., TMP–SMX, ampicillin, or chloramphenicol).[46] By the late 1990s, short-course fluoroquinolone therapies used in parts of Asia were associated with clinical failures in up to 50% of patients.[43] Microbiologic evaluation revealed these isolates were resistant

---

to nalidixic acid and had higher ciprofloxacin MICs (0.125–1 mcg/mL) compared to Salmonella that was fully susceptible to ciprofloxacin (MICs of <0.03 mcg/mL).[47] Gatifloxacin, a newer generation fluoroquinolone (no longer marketed in the United States) with lower MICs compared to ciprofloxacin (0.19 vs. 0.5 mcg/mL, respectively) cured greater than 95% of children with typhoid fever, most of whom were infected with nalidixic acid–resistant S. typhi.[15] In areas with a high prevalence of nalidixic acid–resistant S. typhi, alternatives to fluoroquinolones include azithromycin and selected third-generation cephalosporins.

Azithromycin

Azithromycin is effective for patients with mild-to-moderate typhoid fever.[48] Azithromycin (20 mg/kg/day) for 7 days cured greater than 95% of children with uncomplicated typhoid fever in Vietnam where 96% of S. typhi are nalidixic acid–resistant; fever clearance time was 106 hours and there were no relapses.[15] In contrast, lower azithromycin doses (10 mg/kg/day) in the setting of nalidixic acid–resistance are associated with lower cure rates (82%).[49] Concerning is the identification of azithromycin-resistant S. typhi[50] and non-response to azithromycin.[51]

α-lactams and Tigecycline

Cefixime, an oral third-generation cephalosporin, is variably effective for the treatment of typhoid fever. Failure rates range from 4% to 27%[50] and some experts do not recommend its use for the treatment of typhoid fever.[43] The lower clinical response to cefixime may be related to the poor intracellular penetration of the β-lactam because the intracellular compartment is the primary site of S. typhi colonization.[52]

Ceftriaxone, an intravenous third-generation cephalosporin, is recommended for the treatment of severe typhoid fever[44] with the caveat that longer treatment courses are recommended to prevent relapse of infection. In patients with bacteremia caused by ceftriaxone-susceptible isolates, relapse of infection was higher among patients treated with a 7-day course of ceftriaxone versus azithromycin, 14% versus 0%, respectively.[53] No relapses were reported when a longer course (14 days) of ceftriaxone was used for infection caused by multidrug-resistant S. typhi.[54] Patients treated with ceftriaxone may remain febrile for as long as 10 days.[55] Ceftriaxone-resistant S. typhi have been reported in India, the Philippines, China, the United States, and elsewhere.[56] Potential alternatives to ceftriaxone include carbapenems (imipenem, meropenem, and ertapenem) and tigecycline, though clinical data are lacking.[48]

TREATMENT—SEVERE VERSUS UNCOMPLICATED TYPHOID FEVER

CASE 69-11, QUESTION 3: What specific empiric antibiotic regimen would you recommend for the treatment of B.C.'s complicated (severe) typhoid fever? How would her treatment differ if she had uncomplicated typhoid fever?

For complicated typhoid fever, empiric therapy with ceftriaxone is recommended.[57] Once susceptibility data are available, treatment options include 10 to 14 days of ceftriaxone (1–2 grams IV once daily) continued for at least 7 days after defervescence to minimize the risk for relapse,[48] or a fluoroquinolone for 10 to 14 days.[44]

Uncomplicated typhoid fever is typically treated in the outpatient setting.[44] Empiric oral regimens include azithromycin 500 mg daily × 5 to 7 days,[44] or a fluoroquinolone (e.g., levofloxacin 500 mg once daily or ciprofloxacin 500 mg twice daily).[3] For children, azithromycin or ceftriaxone is recommended.[3] Interestingly, with the reduction in MDR S. typhi in some areas, ampicillin, amoxicillin, TMP–SMX, or chloramphenicol are again options for susceptible isolates.[44]

ADJUNCTIVE TREATMENT

CASE 69-11, QUESTION 4: Besides the administration of antibiotics, what adjunctive therapies could benefit B.C. for the treatment of severe typhoid fever?

Enteric encephalopathy, i.e., altered mental status, is associated with a mortality rate as high as 56% if effective treatment is not promptly administered.[58] In patients with enteric encephalopathy, retrospective data report improved survival when appropriate antimicrobial therapy is combined with high-dose dexamethasone (3 mg/kg IV followed by 1 mg/kg every 6 hours IV for eight doses).[58] The mechanism of action of dexamethasone in enteric encephalopathy is not known.[58]

CASE 69-11, QUESTION 5: Fourteen months after discharge from the hospital, B.C. remains free of symptoms associated with typhoid fever, but follow-up testing reveals she continues to excrete S. typhi in her stools. Additionally, their adult son who has dinner with them every Sunday, presents to his clinic doctor with fever, headache and chills, and is confirmed to have uncomplicated typhoid fever. He has no significant past medical history and has no recent travel history. How might her son have acquired typhoid fever? What treatment recommendations can be provided to this family?

Unlike his mother B.C., her son has no travel history to an area where typhoid fever is endemic. Instead, he is likely to have contracted typhoid fever from consuming foods prepared by his mother who is now a chronic carrier of S. typhi. Most patients with typhoid fever continue to excrete S. typhi in their stools for 3 to 4 weeks after recovery from their illness. However, 1% to 3% of persons like B.C. become chronic carriers who continue to excrete Salmonella from stool or urine for more than 1 year after infection and serve as reservoirs for spreading infection. Unlike for non-typhoidal salmonellae, humans are the only natural host and reservoir for S. typhi.[55] B.C.'s risk factor for becoming a chronic carrier is her history of gallstones which allows the sequestration of organisms within her abnormal biliary tract.

CHRONIC TYPHOID CARRIERS

Treatment

CASE 69-11, QUESTION 6: What therapeutic options are available to cure B.C.'s chronic carrier state?

Treatment options for chronic S. typhi carriers like B.C. include a prolonged course of antibiotics, cholecystectomy, or suppressive antimicrobial therapy.[42] Fifty to ninety percent of chronic carriers may be cured after prolonged courses of antibiotics,[59–62] although efficacy may be lessened when anatomic abnormalities (e.g., cholelithiasis) are present.[59] Relapse is usually detected within the first several months after completing antimicrobial therapy[63] but can occur up to 24 months after completing therapy.[64] For susceptible S. typhi, curative oral antimicrobial regimens include amoxicillin 2 g 3 times daily for 28 days,[61] ampicillin 1 g 4 times daily for 90 days,[60] ampicillin 1.5 g 4 times daily plus probenecid for 6 weeks,[59] TMP–SMX 160/800 mg twice a day for 3 months,[62] ciprofloxacin 500 to 750 mg twice a day for 3 to 4 weeks,[65–67] or norfloxacin 400 mg twice daily for 4 weeks.[68]

Prevention

CASE 69-11, QUESTION 7: B.C.'s sister is planning a trip to the Indian subcontinent and is concerned about acquiring typhoid fever. What can she do to reduce her risk for becoming infected?

The U.S. Centers for Disease Control and Prevention recommends vaccination for travel to areas where the risk for S. tyhi is increased including many Asian, African, and Latin American countries.[69] In the United States, two licensed vaccines are available to protect against S. typhi but not against S. paratyphi. The intramuscular vaccine for persons older than 2 years of age is 55% effective in preventing typhoid fever; adverse effects include local pain and swelling, fever, and headache.[69] The oral live-attenuated vaccine Ty21a vaccine (series of 4 doses) for persons older than 6 years of age is well tolerated, and it affords a protective efficacy rate around 55%.[69] Since the oral vaccine is a live-attenuated vaccine, it should not be administered to immunocompromised persons. Additionally, to ensure full vaccine activity, the live-attenuated vaccine should not be given until at least 3 days after the last dose of an antimicrobial, and if possible, antimicrobials should not be initiated within 3 days of the last dose of the oral vaccine; longer intervals should be considered for long-acting agents such as azithromycin.[69]

Finally, because the protective efficacy of available vaccines against S. typhi is not 100%, and because neither vaccine is licensed to protect against S. paratyphi which in some Asian countries accounts for up to 50% of blood isolates from patients with enteric fever,[70] it is still necessary to reinforce the importance of good hygiene and the avoidance of foods with a high risk for being contaminated with enteropathogens.

SHIGELLA SPECIES

Shigella are gram-negative intracellular bacterial pathogens belonging to the Enterobacteriacae family. They are the most frequent cause of dysentery, which is an inflammatory diarrheal illness characterized by bloody or mucoid stools with abdominal cramps. Of the four Shigella species, severe dysentery is most commonly caused by Shigella dysenteriae followed by Shigella flexneri, whereas milder illness characterized by watery diarrhea with or without blood is typically caused by Shigella sonnei and Shigella boydii.[71]

Shigellosis—Severe Illness

CLINICAL PRESENTATION

CASE 69-12

QUESTION 1: M.T. is a 60-year-old, ill-appearing man hospitalized for bloody diarrhea and fever. Two days before admission he noted the onset of fever, abdominal cramps, and six to seven non-bloody, watery stools. His diarrhea has since worsened to 10 to 12 small-volume stools with blood and mucus, and he now complains of painful straining while passing his stools. His history of present illness is significant for returning 3 days ago from a business trip to Indian subcontinent. During the business portion of the trip, he remained at the hotel where all his meals were prepared by hotel staff well trained in the sanitary preparation of foods. However, on the day of his departure he opted to mingle with local residents to get a first-hand taste of native foods and beverages from street vendors. M.T. lives alone in Florida, has no significant medical history or drug allergies, and takes no medications. On admission, his temperature is 101°F and physical examination reveals a critically ill man with severe abdominal tenderness. Why is M.T.'s history of present illness and clinical presentation consistent with the diagnosis of dysentery, most likely caused by S. dysenteriae type 1.

M.T.'s diagnosis of dysentery, likely caused by S. dysenteriae type 1 is consistent with his recent travel to the Indian subcontinent where S. dysenteriae type 1 is both epidemic and endemic,[71] primarily as a consequence of inadequate systems for disposal of sewage.[71] M.T. likely became infected from the consumption of contaminated foods or beverages prepared by local street vendors, by person-to-person contact with symptomatic persons with diarrhea, or from asymptomatic persons continuing to excrete shigellae from their stool.[72] As few as 10 to 100 shigellae can cause illness[71] in healthy hosts, explaining why shigellosis is a very contagious infection.

Once ingested virulence factors allow shigellae to evade detection by the immune system and invade colonic and rectal epithelium. Enterotoxin production causes fluid secretion into the intestinal lumen and cytotoxin production causes cell death; both toxins lead to the severe clinical manifestations of shigellosis.[71]

As with M.T., within 24 to 48 hours after ingestion of Shigella bacteria symptoms of dysentery begin and include fever, fatigue, malaise, and anorexia.[72] Watery diarrhea generally precedes dysentery, and frequently is the only manifestation of mild infection.[72] Progression to dysentery may follow within hours to days and is characterized by frequent, small-volume, bloody, and mucoid stools; abdominal cramps; and tenesmus which is described as painful straining when passing stools.[72] Hemolytic uremic syndrome (HUS) is a serious complication of shigellosis, occurring in up to 13% of patients with dysentery caused by S. dysenteriae type 1. HUS is a consequence of the production of shiga-toxin 1, most commonly produced by S. dysenteriae but also rarely by S. flexneri.[71] Longer-term health complications of diarrheal illness caused by invasive pathogens like Shigella species, as well as Salmonella and Campylobacter species, include postinfectious irritable bowel syndrome[73] or reactive arthritis.[74]

TREATMENT

CASE 69-12, QUESTION 2: Would M.T. benefit from antimicrobials to treat the bloody diarrhea and fever (dysentery), presumably caused by S. dysenteriae type 1?

For several reasons, M.T. would benefit from antimicrobial therapy for dysentery presumably caused by S. dysenteriae type 1. First, effective antimicrobial therapy reduces the average duration of illness from 5 to 7 days to about 3 days[72] and reduces the risk of death and serious infection-related complications. Within 48 hours of starting treatment M.T. should notice a reduction in stool frequency, volume of bloody stools, and fever. Second, effective antimicrobial therapy quickly reduces the carriage and excretion of shigellae, thus limiting the spread of infection. Despite the aforementioned benefits of antimicrobial therapy, there has been concern that antimicrobials could increase the risk for developing HUS. However, Bennish et al.[75] reported that early administration of effective antimicrobials (i.e., within 3–4 days of the onset of dysentery) is associated with a low risk for developing HUS.

CASE 69-12, QUESTION 3: What empiric antimicrobial regimens are available for the treatment of shigellosis?

Shigella species are well known for rapidly developing resistance following exposure to antimicrobials; therefore, selection of empiric therapy should be based on local antimicrobial susceptibility patterns.[71]

Ampicillin, TMP–SMX, and Nalidixic Acid

During the 1960s to 1980s, ampicillin, TMP–SMX, or nalidixic acid were the standard treatments for shigellosis. During the 1990s, multidrug-resistant (i.e., resistance to ampicillin, TMP–SMX, and chloramphenicol) Shigella precluded their empiric use for shigellosis, but as these multidrug-resistant isolates remained susceptible to fluoroquinolones, these agents became the drugs of choice for this infection.[71]

Fluoroquinolones

In adults, oral ciprofloxacin 500 mg twice daily for 3 to 5 days is effective against multidrug-resistant S. dysenteriae type 1 infection in the setting where all isolates are susceptible to ciprofloxacin and nalidixic acid.[10] With the widespread introduction of fluoroquinolones as the drugs of choice for the treatment of shigellosis, not unexpectedly, quinolone-resistant shigellae have emerged.[76] Ciprofloxacin resistance in Shigella species from Asia and Africa has progressively increased from 0.6% prior to 2000 to 29.1% during 2007 to 2009.[77] Although the prevalence of ciprofloxacin-resistant Shigella remains low (less than 5%) in Europe and America,[77] international travel is strongly associated with the importation and subsequent circulation, within the United States, of ciprofloxacin-resistant Shigella sonnei[78] and other multi-drug resistant Enterobacteriacae.[79]

Azithromycin

In the setting of epidemic dysentery caused by S. dysenteriae type 1, similar clinical outcomes were observed in adults treated with a single 1 g oral dose of azithromycin or multiple doses of ciprofloxacin (500 mg orally twice daily for 3 days). In this study, the mean number of days until resolution of symptoms after starting therapy was similar (2.5 days for azithromycin vs. 2.3 days of ciprofloxacin) but only 17% of isolates were nalidixic acid–resistant.[80]

In adults with moderate-to-severe shigellosis caused by multidrug-resistant Shigella species, clinical efficacy is similar with oral azithromycin (500 mg on day 1, then 250 mg daily for 4 days) or oral ciprofloxacin (500 mg every 12 hours for 5 days), 89% versus 82%, respectively ($P > 0.2$).[81] In a subgroup analysis, a greater proportion of patients infected with S. dysenteriae type 1 failed therapy with either azithromycin (29%) or ciprofloxacin (17%), compared with patients infected with other Shigella species (failure rate of 6% for either antibiotic).[81] Nearly all (97%) of the S. dysenteriae type 1 isolates were nalidixic acid–resistant (median ciprofloxacin MIC of 0.125 mcg/mL) whereas only 6% of other Shigella species were nalidixic acid–resistant (median ciprofloxacin MIC of 0.016 mcg/mL).

Concerning is the intercontinental spread through sexual transmission of azithromycin-resistant shigellosis and treatment failure following azithromycin therapy.[82] S. sonnei with reduced susceptibility to azithromycin remains susceptible to ceftriaxone,[83] and ceftriaxone has successfully treated a patient with azithromycin-resistant shigellosis failing azithromycin therapy.[84]

β-lactams

The oral third-generation cephalosporin cefixime is unreliable for the treatment of shigellosis, with failures reported in 11% to 47% of patients.[85] Parenteral ceftriaxone and cefotaxime have excellent in vitro activity against Shigella species and have been used alone[39] or with amikacin[46] for patients failing ciprofloxacin therapy. Though uncommon, ceftriaxone-resistant Shigella have been reported in Asia.[71] Ongoing surveillance to detect changes in antimicrobial susceptibility among Shigella species is needed to direct local empiric treatment recommendations.

CASE 69-12, QUESTION 4: Should loperamide be started in patients with dysentery?

The role of antimotility drugs in patients with dysentery has been debated, the concern being that prolonging the clearance of pathogens from the intestinal tract could worsen the severity of illness. However, loperamide (in combination of ciprofloxacin) has been safely used in non-critically ill adults with bacillary dysentery primarily caused by Shigella species, decreasing the number of unformed stools and shortening the duration of diarrhea; fever was not prolonged in these patients.[9] However, the authors stress that all Shigella isolates in the study were susceptible to the antimicrobial used (i.e., all isolates were susceptible to ciprofloxacin and nalidixic acid) and none of the patients were critically ill; thus, it would not be prudent to extrapolate the findings from this study to critically ill patients like M.T.[9]

CASE 69-12, QUESTION 5: What empiric antimicrobial regimen could be started in patients like M.T. with severe dysentery, likely caused by Shigella species?

Ciprofloxacin, azithromycin, and ceftriaxone are the primary agents used for the treatment of shigellosis,[3],[76] though resistance to all of these agents has been reported. In the setting of severe dysentery associated with nausea and vomiting, parenteral ceftriaxone is a reasonable empiric option.[71] Fluoroquinolones are a less desirable option given the widespread prevalence of fluoroquinolone-resistant Shigella species in areas including the Indian subcontinent[77] where M.T. likely became infected.

Shigellosis—Mild Illness

CLINICAL PRESENTATION TREATMENT

CASE 69-13

QUESTION 1: F.F. is a 30-year-old, previously healthy woman, presenting to her physician with non-bloody, watery diarrhea of 3 days' duration. Her history of present illness is significant for the following: 2 days before the onset of her gastrointestinal symptoms she visited with her 4-year-old nephew in California who was recovering from an intestinal illness caused by S. sonnei acquired at his day-care center. F.F. has no significant medical history. Overall, she feels better compared to the previous day and is afebrile. How does F.F.'s clinical presentation of shigellosis differ from that of M.T. (Case 69-12, Question 1)? Should F.F. be treated with antimicrobials for her presumed, mild case of shigellosis?

TREATMENT

Compared to M.T., F.F. is experiencing a much milder, and likely self-limiting case of shigellosis. In industrialized countries, risk factors for shigellosis include settings where individuals are in close contact such as in child-care centers, military barracks, and institutional housing.[72] International travel[78] and sexual transmission in men who have sex with men[82] are other means of spreading shigellosis. Secondary attack rates as high as 40% occur within 1 to 4 days after exposure to the primary case; infected persons may continue to asymptomatically shed Shigella in stool following recovery from their illness.

S. sonnei accounts for 90% of shigellosis in developed countries. As most patients have a mild and self-limiting illness, antimicrobials are not generally required. However, from a public health standpoint they are often prescribed to shorten the duration of illness to reduce the infectious period.[86] On the other hand, with the emergence of multidrug-resistant Shigella species, some experts favor reserving antimicrobials for only severely ill persons.[87]

Empiric antimicrobial options include a 3-day course of either ciprofloxacin 500 mg orally twice daily or azithromycin 500 mg orally once daily; ceftriaxone can also be used.[87] Clinical improvement may be evident within 24 hours.[71]

PREVENTION

Prevention of shigellosis requires good hygiene including proper hand washing and reducing fecal–oral exposure during sexual contact.[88] Development of an effective vaccine has been limited by poor vaccine immunogenicity, decreased vaccine protection because of the changing prevalence of infection caused by non-vaccine serotypes and adverse effects.[71]

CAMPYLOBACTER JEJUNI

Clinical Presentation

CASE 69-14

QUESTION 1: M.U. is a 20-year-old, previously healthy woman presenting to the Student Health Center with the following complaints for the past 24 hours: malaise, fever, diarrhea, abdominal pain, and bloody diarrhea. One day before the onset of symptoms, she dined at a restaurant near campus, noting that the chicken she ate was not thoroughly cooked. She has no significant medical history, no recent travel history, and is a full-time student at a university in the United States. On physical examination, M.U. is not ill appearing. The physician tells her that during the past week several students with gastrointestinal symptoms similar to hers have been diagnosed with C. jejuni gastroenteritis, and all had recently eaten at the same restaurant. Why is M.U.'s history of present illness and clinical presentation consistent with Campylobacter gastroenteritis?

M.U.'s presumptive diagnosis of Campylobacter gastroenteritis is consistent with her recent history of eating undercooked chicken at a restaurant associated with an ongoing outbreak of Campylobacter gastroenteritis. In industrialized nations, the most important risk factor for acquiring Campylobacter infection is the consumption of contaminated undercooked poultry, dairy products, unpasteurized foods, or contaminated water.[89] Prevention of Campylobacter infection involves careful food preparation and cooking practices.[90]

Beginning 24 to 72 hours after consumption of contaminated foods, clinical manifestations of Campylobacter gastroenteritis typically include diarrhea, fever, and abdominal cramps with either loose and watery or bloody stools.[89] Postinfectious complications of C. jejuni gastroenteritis include Guillain–Barré syndrome, reactive arthritis, and postinfectious irritable bowel syndrome; the latter associated with diarrhea lasting more than 7 days.[89]

Treatment

CASE 69-14, QUESTION 2: Would M.U. benefit from antimicrobial therapy to treat her Campylobacter gastroenteritis?

Because C. jejuni gastroenteritis is typically an acute, self-limiting illness resolving within 3 to 7 days,[91] antibiotic therapy is usually not necessary.[89] Antibiotics are recommended for patients with symptoms lasting longer than 1 week, high fevers, bloody stools, pregnant women, or immunocompromised hosts.[92] As M.U.'s clinical presentation includes fever with bloody stools, antimicrobial therapy is warranted. Effective antimicrobial therapy shortens the duration and the severity of illness by a mean of 1.3 days, and it is most beneficial when started with 3 days of the onset of illness.[89]

CASE 69-14, QUESTION 3: What empiric antimicrobial therapies could be initiated to treat M.U.'s presumed case of C. jejuni gastroenteritis?

MACROLIDE/AZALIDE

Macrolides (or an azalide) remain the drugs of choice for the treatment of Campylobacter gastroenteritis.[3] Macrolide resistance has remained relatively stable around 5%,[89] but depending on geographic location, higher macrolide resistance has been reported from Eastern Europe and China (5%–11%)[93] and India (22%).[94]

FLUOROQUINOLONES

Once considered the drugs of choice for Campylobacter infection, fluoroquinolones are no longer first-line options as a consequence of widespread fluoroquinolone resistance, largely attributed to their use in veterinary medicine and food animals (e.g., poultry); the latter practice has since been banned in the United States.[93] Fluoroquinolone-resistant C. jejuni exceeds 80% in Spain, Thailand, and Hong Kong, and it is about 50% in selected European Union States.[95] In the United States, the prevalence of ciprofloxacin-resistant C. jejuni remained between 20% and 30% from 2007 to 2011.[89],[93],[96] However, higher quinolone-resistance among Campylobacter isolates in international travelers returning to the United States compared to non-travel-associated isolates (60% vs. 13%)[93] underscores the need to consider local resistance patterns from where infection was acquired, when selecting empiric antimicrobial therapy for returning travelers.

Recommended oral treatments for C. jejuni gastroenteritis for adults are azithromycin 500 mg once daily for 3 days or erythromycin 500 mg 4 times daily for 5 days.[3] Children may be treated with azithromycin 10 mg/kg/day once daily for 3 to 5 days or erythromycin 30 mg/kg in two to four divided doses for 3 to 5 days.[3] On the basis of M.U.'s medical history and clinical presentation, empiric therapy with oral azithromycin can be started.

TRAVELERS' DIARRHEA

Of the nearly one billion people traveling each year from industrialized countries to developing areas of the world, approximately 10% to 60% will experience an acute self-limiting episode of travelers' diarrhea (TD).[14],[97] Long-term postinfectious complications occur in a small proportion of returning travelers.[14] Experts recommend pretravel education focusing on the prevention of TD and instructions for the self-treatment of TD at the onset of illness.[98]

CASE 69-15

QUESTION 1: W.D. and B.D. are healthy 23-year-old females beginning a 2-week backpacking trip through Latin America. Prior to their departure both travelers attended a travel clinic where they received instructions to minimize their risk for TD, and a travel kit including instructions and medications for the self-treatment of TD. On the day of their arrival, both travelers seek out local street vendors, sampling their fresh fruits, vegetables, prepared foods, and unbottled beverages.

On the second day of their vacation both travelers are not feeling well. W.D. notes only the passing of two to three watery stools without blood, and mild nausea. In contrast, B.D. is feeling much worse noting the passing of six to seven loose, bloody stools, abdominal cramps, and feeling "feverish." Neither traveler feels dizzy or thirsty, and both are able to continue drinking unbottled water and juices. What are their risk factors for TD and why are their clinical presentations consistent with this diagnosis?

Risk Factors

Both travelers have several risk factors for acquiring TD. First, their travel to Latin America, a destination considered "high-risk" for TD (i.e., ≥20% risk within the first 2 weeks of travel); other

---

high-risk destinations include South Asia and West/Central Africa.[14] Second, because the highest risk for TD is during the first 2 weeks of travel, their recent arrival to an at-risk destination increases the likelihood for infection; the risk for TD lessens during the second (9.9% risk) and third (3.3% risk) weeks of travel.[14] Third is their travel style of eating foods with a high-risk for contamination with enteropathogens such as foods from local street vendors and drinking unbottled beverages. Additional high-risk foods include ice cubes, raw milk, unpeeled fruits and vegetables, uncooked foods, moist foods; foods remaining at room temperature for prolonged periods of time, allowing bacteria to multiply or release their enterotoxins[99]; use of acid-inhibiting medications allowing acid-susceptible enteropathogens to pass through to the intestines; and genetic predisposition.[14]

Clinical Presentation

TD is defined as three or more loose, unformed stools per day plus at least one symptom of enteric infection such as abdominal cramps, nausea, vomiting, fever, fecal urgency, tenesmus, or the passage of bloody or mucoid stools. Like in these travelers, illness typically begins within 24 to 48 hours after consuming fecally contaminated foods. Left untreated, TD is generally a self-limiting illness lasting 4 to 5 days.[14]

General Management

CASE 69-15, QUESTION 2: What general approach should W.D. and B.D. take to manage their diarrheal illnesses?

Realizing that their symptoms are consistent with TD, both travelers review their pretravel information for the self-management of TD.

Hydration

To replace fluid and electrolyte losses they should continue to drink only bottled or boiled liquids such as tea, broth, carbonated beverages, and fruit juices.[99] Electrolytes can be replaced by eating salted crackers or similar sources of sodium chloride. For travelers able to drink fluids ad libitum, a modified World Health Organization oral rehydration solution offers no additional benefit over the administration of loperamide alone.[100] Neither traveler has symptoms indicative of significant dehydration such as thirst, dizziness, or altered mental status.

SAFE FOODS—“PEEL IT, BOIL IT, OR FORGET IT”

Travelers should avoid consuming foods with a high risk for contamination with enteropathogens such as raw vegetables, fruit they have not peeled themselves, cooked food not served steaming hot, and tap water.[101] Instead, they should only eat fruits that they have peeled themselves or that have been adequately washed, and well-cooked foods served steaming hot. Enteropathogens are killed at 100°C and foods served piping hot at 60°C are generally safe.[14]

Despite adherence to dietary restrictions and precautions, prevention of TD is not always possible, likely reflecting the difficulty with adhering to sanitary standards for the preparation and serving of foods, the lack of facilities for employees to wash their hands after going to the bathroom, or the lack of screens or windows to prevent flies from contaminating foods.[14]

SELF-TREATMENT OF TRAVELERS’ DIARRHEA

Antimotility agents alone provide rapid relief of symptoms but do not cure the infection, whereas antimicrobials alone will cure the infection but symptoms may persist for a longer time.[99] In the appropriate setting, antimotility drugs plus antibiotics provide the fastest relief of diarrheal symptoms.[99] Selection of a self-treatment plan is, in part, based on the traveler's severity of illness and manifestations of their diarrheal illness.

Microbial Etiology, Clinical Manifestations, and Treatment Options

CASE 69-15, QUESTION 3: For travelers with the following manifestations of TD, (a) watery diarrhea without blood or fever, or (b) bloody diarrhea or fever, or (c) diarrhea while taking chemoprophylaxis, what are the common microbial etiologies, and what treatment options are available to manage these diarrheal syndromes?

The microbial etiology of TD is recognized in 50% to 94% of patients, with bacteria most commonly identified; viruses and parasites are less frequently isolated.[14] For travelers to developing countries, the most common enteropathogen is enterotoxigenic E. coli (ETEC), followed by enteroaggregative E. coli (EAEC), diffusely adherent E. coli, noroviruses, rotaviruses, Salmonella species, C. jejuni, and Shigella species.[14] The likely enteropathogen afflicting individual travelers can in part be predicted by the clinical manifestations of the diarrheal illness and the travel destination (information which is helpful for selecting an appropriate self-treatment plan).[102]

WATERY DIARRHEA WITHOUT FEVER OR BLOODY DIARRHEA

ETEC is suspected in the setting of acute watery diarrhea, especially in travelers to Latin America and the Caribbean (≥35% of reported pathogens), Africa (25%–35% of reported pathogens), and South Asia (15%–25% of reported pathogens).[14] ETEC produce enterotoxins that stimulate the intestinal mucosa to secrete fluid into the gut lumen, leading to diarrheal stools.

Loperamide, Diphenoxylate/Atropine, Bismuth Preparations

Loperamide alone can be considered in patients with a mild diarrheal illness, e.g., two loose stools and mild symptoms,[103] without fever or bloody stools.[101] Loperamide rapidly relieves diarrheal symptoms, often within <24 hours[101] and is better tolerated than diphenoxylate/atropine. Mild diarrheal illness may be less likely to be infectious in etiology, but instead because of noninfectious causes such as anxiety, diet changes, and stress.[103] Bismuth subsalicylate is moderately effective in improving diarrheal symptoms.[14]

Alternatively, travelers on a short and critical trip (e.g., business) might consider the addition of an antibiotic. However, the potential adverse consequences of antimicrobial therapy such as the risk for adverse drug events, additional cost, and antimicrobial resistance should also be considered. A recent prospective study reported that depending on the travel destination, the risk for a traveler with diarrhea becoming colonized with extended-spectrum beta-lactamase producing Enterobacteriacae was greatest (28%–80%) if an antimicrobial was taken versus if no antibiotic was taken (8%–47%).[79] After returning home up to 24% of travelers remain colonized at 6 months and 10% remain colonized at 3 years.[79] Consequently, some experts do not recommend antimicrobials for mild-to-moderate disease nor for the prevention of TD.[79]

Antimicrobials Alone

Rifaximin, ciprofloxacin or levofloxacin, or azithromycin[102] are recommended for travelers with watery diarrhea without fever or dysentery[102] (Table 69-3). For travelers to Mexico[104],[105] or Kenya,[106] where ETEC is a frequent cause of TD, a single dose of ciprofloxacin 500 mg, azithromycin 1 g, or levofloxacin 500 mg decreased the median time to passage of the last unformed stool to 22 to 33 hours versus 54 to 66 hours for travelers given placebo.[107] For travelers to Mexico or India, oral rifaximin 200 mg 3 times daily or ciprofloxacin 500 mg twice daily for 3 days significantly reduced the median time to passage of the last unformed stool to 32 hours and 29 hours, respectively, versus 66 hours for travelers taking placebo.[108] Rifaximin is not systemically absorbed, is well tolerated and has a low potential for the development of antibiotic resistance.[109]

Table 69-3

Therapy for Travelers' Diarrhea in Adults

Drug	Treatment
Ciprofloxacin	500 mg twice daily for 1–3 days[a]
Levofloxacin	500 mg daily for 1–3 days[a]
Azithromycin	1,000 mg in a single dose or 500 mg once daily × 3 days
Rifaximin	200 mg 3 times daily for 3 days

[a] Single dose may be effective. If diarrhea improves 12–24 hours after the first dose, the antibiotic can be stopped; otherwise, may continue antibiotic for up to 3 days.

Source: Hill DR, Beeching NJ. Travelers' diarrhea. Curr Opin Infect Dis. 2010;23:481; DuPont HL et al. Expert review of the evidence base for self-therapy of travelers' diarrhea. J Travel Med. 2009;16:161.

Antimotility Drugs Plus Antimicrobials

The combination of antimotility drugs plus antimicrobials provide the fastest relief of diarrheal symptoms. The antimotility drug quickly acts to reduce the number of stools, whereas the antimicrobial cures the infection.[104] In military personnel stationed in Turkey with TD primarily caused by ETEC, the median time to the passage of the last unformed stool was shortened to as little as 3 hours in recruits taking oral loperamide (4 mg initially, then 2 mg as needed; maximum 16 mg/day) plus either levofloxacin (single 500-mg dose) or azithromycin (single 1-g dose).[110] In otherwise healthy US students at least 18 years old attending school in Mexico, the combination of rifaximin (200 mg orally 3 times daily for 3 days) plus loperamide (4 mg initially, then 2 mg after each unformed stool) relieved diarrheal symptoms faster (27 ± 4.13 hours) than rifaximin alone (32.5 ± 4.14 hours) or loperamide alone (69 ± 4.11 hours).[109]

BLOODY DIARRHEA WITH OR WITHOUT FEVER, OR DIARRHEA WHILE TAKING CHEMOPROPHYLAXIS[102]

Invasive pathogens including Shigella, Campylobacter, and less commonly Salmonella, non-cholera Vibrios and Aeromonas species are suspected in the setting of acute bloody diarrhea with fever. Campylobacter species are frequent causes of TD in travelers to Southeast Asia (25%–35% of reported pathogens) and South Asia (15%–25% of reported pathogens).[14]

Antimicrobials Alone

A comparative study reported the highest cure rate with a single dose of azithromycin 1 g (96%), followed by 3 days of either azithromycin 500 mg daily (85%) or levofloxacin 500 mg daily (71%).[110] The lower cure rate with levofloxacin was because of infection with levofloxacin-resistant Campylobacter species. Nausea during the 30 minutes after receipt of the first antimicrobial dose was more common in persons given 1 g of azithromycin versus the other regimens (14% vs. <6%, respectively).[110]

Rifaximin should not be used in patients with diarrhea complicated by fever and bloody stools, being ineffective against invasive enteropathogens, e.g., Salmonella, Shigella, and Campylobacter species.[102]

CASE 69-15, QUESTION 4: Based on the symptoms each traveler is experiencing, what drug therapies are available for W.D. and B.D. that can be considered to reduce the duration and severity of their TD?

For travelers with mild watery diarrhea without fever or bloody stools (like W.D.), loperamide can be used, often relieving symptoms in less than 24 hours.[101] If improvement is not evident within 12 hours, an antimicrobial could be started.[103]

For travelers with moderate-to-severe diarrhea with fever or bloody stools (like B.D.), antimicrobial therapy is recommended to shorten the duration and severity of the diarrheal illness.[101] Treatment options include a fluoroquinolone or azithromycin (Table 69-3). Azithromycin is recommended for travelers to areas with a high prevalence of fluoroquinolone-resistant Campylobacter species,[101] including

Thailand (93%), Nepal (71%), Asia (70%), Latin America (61%), and Africa (31%),[102] or for travelers not responding within 48 hours to a fluoroquinolone.[101] Rifaximin is not effective for TD caused by invasive enteropathogens[14] and not recommended for B.D.

POSTINFECTIOUS COMPLICATIONS OF TD

CASE 69-15, QUESTION 5: Three weeks after returning from their trip, unlike W.D. who is free of intestinal symptoms, B.D. continues to have episodes of loose stools and abdominal discomfort, for which she seeks medical attention. On physical examination her vital signs are stable and she is afebrile. The physician believes her symptoms are consistent with postinfectious irritable bowel syndrome (PI-IBS). What are B.D.'s risk factors for PI-IBS and why is her clinical presentation consistent with this diagnosis? What therapies can be recommended to manage her symptoms?

Clinical Presentation and Risk Factors

Postinfectious complications of TD include reactive arthritis and Guillain–Barré syndrome which are associated with C. jejuni infection and PI-IBS which may occur in 3% to 17% of travelers following a diarrheal episode[14] by invasive pathogens including Campylobacter, Salmonella, and Shigella species.[7] Risk factors for PI-IBS include a severe episode of TD (like B.D.), the number of episodes, pretravel diarrhea, pretravel adverse life events, and infection with heat-labile toxin-producing ETEC.[14]

Management

Treatment of PI-IBS is aimed at providing symptomatic relief; antimicrobials have not been proven to be beneficial and may be harmful.[111] Diarrheal symptoms can be managed with loperamide; if postprandial fecal urgency is problematic, taking loperamide 30 minutes before meals is recommended. Bloating and abdominal discomfort can be managed with simethicone or antispasmodic agents[73]; chronic abdominal symptoms can be managed with low doses of amitriptyline and selective serotonin reuptake inhibitors.[111] About 50% of patients with PI-IBS recover within 6 years, although recovery is less likely in the setting of persistent depression or anxiety.[111]

Prevention of PI-IBS with chemoprophylaxis of TD has not been proven. A recent randomized, double-blind, placebo-controlled study evaluating prophylactic rifaximin for the prevention of diarrhea in travelers to South and Southeast Asia did not find rifaximin to reduce the occurrence of new-onset IBS. The absence of a benefit could be attributed to inadequate power of the study to detect a true difference; more studies are needed to address this issue.[112]

Prophylaxis

CASE 69-15, QUESTION 6: On hearing of the travels of W.D. and B.D., friends J.G. and T.M. begin planning a similar vacation to Central America, but they want to prevent the occurrence of any diarrheal illness. Neither friend has any significant medical history. Should prophylaxis be recommended for these travelers? What drug therapies can be recommended for the chemoprophylaxis of TD?

CANDIDATES FOR ANTIMICROBIAL PROPHYLAXIS AND SPECIFIC AGENTS

Antimicrobial prophylaxis for TD is recommended when the benefit of prophylaxis outweighs the risks of drug therapy including adverse drug reactions such as photosensitivity with fluoroquinolones, bacterial resistance, and expense.[112] In otherwise healthy persons, TD is typically a self-limiting illness lasting several days, and should it occur, traveler's self-management of TD reduces the time to the last unformed stool to within 24 hours of the onset of illness.[113] For these reasons, routine chemoprophylaxis for TD is not recommended.

Chemoprophylaxis could be considered for travelers at greatest risk for infection or its complications, including persons in whom a short-term illness could ruin the purpose of the trip (e.g., athletes, politicians, lecturers, others); persons in whom a diarrheal illness could complicate an underlying medical problem (e.g., insulin-dependent diabetes mellitus, congestive heart failure, reactive arthritis, inflammatory bowel disease, advanced cancer, or HIV infection); and persons with conditions which increase the risk for enteric infection (e.g., genetic predisposition, gastric disease or surgery, or use of acid-reducing medications).[104] If offered, chemoprophylaxis should not extend beyond 2 to 3 weeks.[14],[101] Thus, these travelers are not candidates to receive antimicrobial prophylaxis for TD. Instead, at the onset of illness, they should follow their self-treatment plan for TD they received from their pretravel clinic visit.

For travelers who are candidates for chemoprophylaxis of TD, the following options are available.

Antimicrobials

Chemoprophylaxis with a fluoroquinolone (ciprofloxacin 500 mg or levofloxacin 500 mg given daily during travel but not exceeding 2–3 weeks and for 2 days after return) is recommended to reduce the incidence of diarrheal illness.[14],[101] However, the current efficacy of fluoroquinolones should be viewed with caution, given rising fluoroquinolone resistance in common enteropathogens[112] including ETEC and EAEC in India, and Campylobacter species in Asia and Latin America.[102] Azithromycin 250 mg daily is an alternative chemoprophylactic agent and preferred for travel to destinations where Campylobacter species is a common cause of TD, e.g., South and Southeast Asia.[101]

Rifaximin is not FDA approved for the prophylaxis of TD, but it has been effective for the prevention of TD in students traveling from the United States to Mexico where ETEC is a common enteropathogen.[114] A more recent randomized, double-blind, placebo-controlled study showed only a modest (48% protection) benefit of rifaximin compared to placebo in otherwise healthy travelers to South and Southeast Asia—areas where enteroinvasive pathogens are frequent causes of TD.

Miscellaneous Agents

Bismuth subsalicylate, two tablets (526 mg/dose) 4 times daily for a maximum of 3 weeks has a protective efficacy of 65% against TD.[115] The problems with BSS because of inconvenient dosing, salicylate content, and unpleasant adverse effects as mentioned before need to be considered.

Probiotics have been studied on the basis of their ability to prevent enteropathogen colonization. The effectiveness of probiotics has not been determined and more studies are needed before these agents can be routinely recommended.[102]

ESCHERICHIA COLI O157:H7

Epidemiology

CASE 69-16

QUESTION 1: P.J., a 3-year-old girl, is brought to the ED because of “stomach pains” and non-bloody diarrhea that has progressed to bloody diarrhea over the past 48 hours. Five days before the onset of diarrhea, the family celebrated her birthday at a fast-food restaurant; P.J.’s parents ate fish sandwiches and P.J. ate a hamburger. P.J.’s mother noted that the hamburger was not thoroughly cooked because the juices from the hamburger were still pinkish. P.J. has no significant medical history. During the week, she attended a day-care center.

On physical examination P.J. is afebrile, with signs of mild-to-moderate dehydration. A stool sample is negative for fecal leukocytes. The physician assesses her illness as bloody diarrhea, possibly caused by Shiga toxin–producing E. coli (STEC). The plan is to admit P.J. to the hospital for hydration, observation, and further workup. What clinical and laboratory findings and epidemiologic history are consistent with the diagnosis of STEC as the cause of P.J.’s illness?

E. coli O157:H7 is a strain of E. coli that produces Shiga toxins as one of its mechanisms of causing GI illness. A second virulence factor of STEC strains is their ability to attach to and damage the intestinal mucosa.[116] These E. coli bacteria cause a wide spectrum of illness, including asymptomatic carriage, mild and non-bloody diarrhea, bloody diarrhea (hemorrhagic colitis), HUS, and thrombotic thrombocytopenia purpura.[117]

E. coli O157:H7 should be suspected in the setting of abdominal cramps with nonbloody diarrhea that progresses to bloody diarrhea over 1 to 2 days.[118] Unlike bloody diarrhea associated with Shigella species or Campylobacter species, fever is often absent or of low grade because this pathogen is not invasive.[119] Patients with severe illness are more likely to have fever, however.[120]

STEC is most commonly spread by consumption of undercooked beef products that are contaminated with E. coli O157:H7, although other modes of acquiring this infection have been reported. The incubation period for this infection is usually 3 to 4 days, which is consistent with P.J.'s recent history of eating undercooked hamburger. In most instances, the illness resolves in 5 to 8 days.[121] Fecal leukocytes may or may not be found in stool samples.[122]

Laboratory Diagnosis

CASE 69-16, QUESTION 2: How can P.J.'s diagnosis of E. coli O157:H7 infection be confirmed?

In the United States, E. coli O157:H7 is the most common STEC serotype associated with this infection.[122] Unlike other E. coli, O157:H7 does not rapidly ferment sorbitol, thus allowing the use of special culture media (Sorbitol-MacConkey) to help in identifying this organism. P.J.'s stool should be cultured using this media. Because of other sorbitol-fermenting organisms and non-O157 STEC, further testing for Shiga toxins or the genes encoding them is increasingly performed.[121],[123]

Hemolytic Uremic Syndrome

CASE 69-16, QUESTION 3: Forty-eight hours after admission to the hospital, P.J. is pale and has developed several "bruises" on her extremities. The nurse recorded only a minimal output of darkened urine during the past 24 hours. New laboratory tests reveal blood urea nitrogen (BUN), 150 mg/dL; serum creatinine (SrCr), 6 mg/dL; serum potassium (K), 6.8 mEq/L; WBC count, 20,000 cells/mm^3; hemoglobin (Hgb), 5 g/dL; platelets, 50,000 cells/mm^3; and urinalysis is positive for blood and protein. The stool specimen sent on admission is positive for E. coli O157:H7. What complication of E. coli O157:H7 infection does P.J. now display?

The new clinical and laboratory findings support the diagnosis of HUS, a well-known complication of STEC infection. HUS is characterized by the triad of thrombocytopenia, microangiopathic hemolytic anemia, and acute renal failure with oliguria.[124] On physical examination, P.J.'s "bruises" on her extremities are consistent with thrombocytopenia, which is confirmed by the low platelet count. Her pale appearance is consistent with anemia and is confirmed by the low Hgb. The dark urine is caused by the color imparted from bilirubin because of red cell lysis (hemolytic anemia). Finally, P.J.'s decreased urine output and increased serum creatinine and BUN concentrations are consistent with renal failure.[125] P.J. has several risk factors for HUS: her age (i.e., children aged <5–15 years, median age 4–8 years), fever, increased peripheral WBC count, and the season of the year (i.e., summer).[120],[124],[126–129] Although not present in this case, other possible risk factors for developing HUS are age >65 years[122] and treatment with antimotility or antidiarrheal agents,[130] although this has not been universally confirmed.[120],[129] The progression of E. coli O157:H7 gastroenteritis to HUS typically becomes apparent about 1 week after the onset of diarrhea.[120],[124],[126] Of children, 3% to 7%[130] may develop HUS, with a mortality rate ranging from 3% to 5%.

In adults, E. coli O157:H7 infection progresses to HUS in as many as 27% of patients, with a higher rate in patients >65 years of age.[120] HUS-related mortality has reached 42% in patients >15 years of age[120]; elderly nursing home patients have a mortality rate of up to 88%.[131]

Treatment

CASE 69-16, QUESTION 4: Would P.J. benefit from drug therapy, including antimicrobial, antimotility, or antidiarrheal agents?

Other than supportive measures to manage the complications associated with illness caused by E. coli O157:H7, no specific drug therapy for this infection exists.[118] In retrospective and prospective studies, antibiotics have not influenced the severity of illness, or the duration of diarrhea or other GI symptoms.[132] When TMP–SMX was started a mean of 7 days after the onset of diarrhea, the duration of E. coli O157:H7 excretion was not altered.[133]

The effect of antibiotic administration on the risk of E. coli O157:H7 complications (e.g., HUS) remains controversial. A prospective cohort study of 71 children with diarrhea caused by E. coli O157:H7 found that antibiotic treatment increased the risk of progression to HUS.[129] Previous publications have supported these findings,[130],[133],[134] whereas others have reported that antibiotics do not increase the risk of progression to HUS.[120],[135] A systematic review of these and other studies revealed no association between antibiotic administration and development of HUS.[136] Antibiotic selection, dosing, timing of administration, small sample sizes, and a lack of placebo use in the selected studies complicate the analysis. Thus, the role of antibiotics in the treatment of E. coli O157:H7 infection remains controversial. Currently, clinicians do not recommend antibiotic treatment for STEC, though active US surveillance reports nearly 2/3 of patients with this diagnosis receive antimicrobial therapy, including 29% of patients receiving therapy after confirmed diagnosis.[137] Despite these numbers, P.J. should not receive antibiotic therapy at this time. Clinicians must carefully weigh empiric antibiotic treatment before an organism has been identified.[136]

Antimotility drugs are not recommended for patients with E. coli O157:H7 infection because they have been variably associated with an increased risk of progression to HUS,[130],[135] although other studies have failed to find an association.[120],[129] Despite these concerns, recent reports suggest up to 31% of patients continue to receive antimotility agents for this infection.[137] Although the explanation for the increased risk is unknown, the reduction of bowel motility may decrease the clearance of organisms from the GI tract, thereby increasing the absorption of toxins. Administration of antimotility drugs within the first 3 days of illness has been associated with a longer duration of bloody diarrhea.[138]

Prevention

CASE 69-16, QUESTION 5: P.J.'s family members want to know what they could have done to prevent this infection. On discharge from the hospital, is it safe for P.J. to return to her day-care center?

STEC is often spread to humans by consumption of contaminated beef products that are not thoroughly cooked.[117] Because thorough cooking kills this organism, meat should be well cooked (i.e., juices from meat should be clear, not pink). In addition, this infection can be acquired by consuming other contaminated foods, including water, unpasteurized milk, apple cider, lettuce, and sprouts.[117],[118]

Finally, because contact with infected persons commonly results in transmission of this infection to others,[130],[131],[134] P.J. should not return to day care until at least 48 hours after her diarrhea has ceased.[132]

CLOSTRIDIUM DIFFICILE INFECTION

Mild-to-Moderate Infection

CLINICAL PRESENTATION AND DIAGNOSIS

CASE 69-17

QUESTION 1: B.W., a 35-year-old woman, is admitted to a 10-bed medical ward for the treatment of Streptococcus pneumoniae meningitis. On arrival, she is started on ceftriaxone (Rocephin) 2 g IV q12 hours and improves over the next few days. On day 7 of antibiotic therapy, she complains of feeling warm, with cramping abdominal pain and diarrhea. She begins passing mucoid, greenish, foul-smelling watery stools, and has a temperature of 101°F. Microscopic examination of a stool sample is positive for fecal leukocytes. The physician's assessment of B.W.'s clinical and laboratory findings is antibiotic-associated diarrhea (AAD), most likely caused by C. difficile. What is the most likely mechanism for this patient's AAD?

ADD is a common complication of antimicrobial therapy.[139] The mechanisms by which antibiotics cause diarrhea include direct allergic and toxic effects on intestinal mucosa, and alterations of GI motility (e.g., erythromycin) and of normal intestinal flora.

Changes in the normal bowel flora can lead to changes in carbohydrate or bile acid metabolism by intestinal bacteria or to overgrowth of pathogenic bacteria, either of which may be followed by diarrhea.[139] Bacteria known to be associated with AAD include C. perfringens, S. aureus, Klebsiella oxytoca, Candida species, and C. difficile. C. difficile infection (CDI) is the most clinically relevant microbial cause and the focus of this section.

A spore-forming, gram-positive anaerobic bacillus, C. difficile can cause a wide spectrum of syndromes, including asymptomatic carriage, diarrhea of varying severity, colitis with or without formation of pseudomembranes, toxic megacolon, colonic perforation, and death.[140]

The pathogenesis of CDI involves disruption of the normal colonic flora, most commonly by antibiotics (Table 69-4). An increasing number of cases in the outpatient setting have been identified without any antibiotic exposure, making additional risk factors difficult to find.[141] Recent data suggest that proton-pump inhibitors may be responsible for CDI.[142],[143] Alteration of the colonic microflora is followed by overgrowth of toxin-producing strains of C. difficile.[139],[140] These toxins, primarily toxins A and B, are responsible for causing colonic inflammation and the clinical manifestations of this infection.[139],[140]

A highly pathogenic strain of C. difficile has been described in outbreaks in the United States and around the world.[140],[144] This strain, labeled BI/NAP1 (or ribotype 027), generally causes more severe disease. Among its increased virulence factors are an increased production of both toxins A and B and a binary toxin. This ribotype has become endemic in some facilities and appears to cause more severe disease even in non-outbreak situations.[145]

Table 69-4

Medications Implicated in Clostridium difficile–Associated Diarrhea

Commonly Implicated
Cephalosporins Clindamycin
Ampicillin

Fluoroquinolones
Less Commonly Implicated
Erythromycin Clarithromycin
Azithromycin
Other penicillins
Trimethoprim–sulfamethoxazole
Rarely Implicated
Aminoglycosides Rifampin
Tetracycline
Vancomycin
Metronidazole
Antineoplastic agents

Source: Owens RC, Jr et al. Antimicrobial-associated risk factors for Clostridium difficile infection. Clin Infect Dis. 2008;46(Suppl 1):S19; Cohen SH et al. Society for Healthcare Epidemiology of America; Infectious Diseases Society of America. Clinical practice guidelines for Clostridium difficile infection in adults: 2010 update by the Society for Healthcare Epidemiology of America (SHEA) and the Infectious Diseases Society of America (IDSA). Infect Control Hosp Epidemiol. 2010;31:431.

CASE 69-17, QUESTION 2: Why is B.W.'s history and presentation consistent with AAD caused by C. difficile?

B.W.'s major risk factor for acquiring CDI is her receipt of an antibiotic within the last 2 weeks. C. difficile is a common cause of nosocomial diarrhea. The clinical and laboratory findings consistent with CDI include mucoid, greenish, foul-smelling watery stools and crampy abdominal pain. Patients usually present with low-grade fevers, but temperature may be >104°F.[146] Peripheral leukocytosis is common with CDI, sometimes with WBC >30,000 cells/mm^3.[146],[147] Fecal leukocytes are variably present in CDI and are not clinically useful for diagnosis.[148]

The onset of symptoms of CDI varies widely from a few days after the start of antibiotic therapy to 8 weeks after the agent is discontinued.[146] Other risk factors for acquiring CDI are admission to a hospital in which C. difficile is endemic or in which there is an ongoing outbreak of CDI.

CASE 69-17, QUESTION 3: How can B.W.'s diagnosis of CDI be confirmed?

Finding toxins in unformed stool of symptomatic patients is the gold standard for diagnosis. Older enzyme immunoassays detecting toxins A/B have largely been replaced by polymerase chain reaction (PCR) tests, because PCR is much more sensitive.[149] An advanced two-step diagnostic method is increasingly recommended. The two-step test first looks for the presence of glutamate dehydrogenase (GDH) antigen as a quick and inexpensive screening test. GDH is produced by all C. difficile strains, so positive GDH tests are then followed by toxin-detecting PCR.[150]

Samples negative for GDH are considered negative and not tested further. Culture, though helpful, is complicated by the fact that of the C. difficile strains isolated from various populations, 5% to 25% do not produce toxins (non-toxigenic) and do not cause colitis or diarrhea.[146] Routine testing for specific C. difficile strains such as ribotype 027 is not typically available in most settings.[149]

Colonoscopy with biopsy is used to make the diagnosis of C. difficile colitis rapidly. The characteristic colonic changes are raised, yellowish nodules or plaque-like pseudomembranes, often with skip areas of normal mucosa.[146] Because the characteristic pseudomembranes may be scattered throughout the colon, the diagnosis of pseudomembranous colitis can be missed with colonoscopy.

CASE 69-17, QUESTION 4: How can B.W.'s CDI be differentiated from enigmatic AAD?

Only 10% to 20% of cases of AAD are positive for toxigenic C. difficile; the remaining cases have an unknown cause and are referred to as simple, benign, or "nuisance" diarrhea.[139] The clinical resolution of benign diarrhea is a self-limited illness that resolves with nonspecific supportive measures and discontinuation of antibiotics. These clinical entities can be differentiated from one another by several objective measures. In hospitalized patients, watery diarrhea, low functional capacity, acid suppression, low albumin, and a WBC >13,000 cells/mm^3 were significant predictors of CDI.[151] Other clinical features that suggest CDI rather than enigmatic diarrhea are constitutional symptoms, lack of an antibiotic dose relationship to the illness, and hospital-wide epidemics of diarrhea.[152]

TREATMENT

CASE 69-17, QUESTION 5: B.W.'s stool sample is positive for both GDH and C. difficile toxin. What is the general plan to treat B.W.'s CDI?

After replacement of fluids and electrolytes, there are several steps to most effectively manage B.W.'s CDI. The first is to discontinue the offending drug (if possible), which in B.W.'s case is probably the antibiotic ceftriaxone. While some data suggest that withdrawal of the precipitating antibiotic and supportive care may be sufficient for mild disease, all available guidelines suggest specific antimicrobial treatment.[150],[153]

Because B.W. is being treated for bacterial meningitis, a life-threatening infection, discontinuing antibiotics is not an option. A second option is to change her antimicrobial therapy to an agent less likely to cause CDI. B.W. is taking a cephalosporin, which, as with ampicillin, amoxicillin, and clindamycin, is frequently implicated as a cause of C. difficile diarrhea (Table 62-4). In contrast, antibiotics, such as TMP–SMX, and aminoglyclosides, are less commonly associated with CDI.[154–156] None of these antimicrobials, however, is a suitable alternative for treating S. pneumoniae meningitis.

B.W. should also receive therapy directed against C. difficile while continuing to take ceftriaxone for the treatment of her bacterial meningitis.

Specific C. difficile–directed Antimicrobials

CASE 69-17, QUESTION 6: What antibiotic should be selected to treat B.W.'s CDI?

The oral agents most commonly used to treat CDI are metronidazole and vancomycin. The differentiation between these two agents is complex and evolving, but it is guided in part by severity of illness[157–161] (Table 69-5). The most optimal definition of severe disease is not well established, but general markers of instability of vital signs with high white counts and changes in albumin and serum creatinine are suggested.[150],[162] In patients categorized as having mild-to-moderate disease severity, metronidazole is generally recommended as the preferred initial agent.[158] In a randomized trial that enrolled patients with CDI and colitis, no significant difference was found in the efficacy of these drugs after 10 days of treatment.[160] Overall, >95% of patients treated for a first episode of CDI with oral metronidazole or vancomycin are expected to respond to therapy.[160],[161] Recent reports have shown increases in C. difficile resistance to metronidazole and vancomycin, but the clinical significance in treatment selection is unknown.[163] Antibiotic sensitivities, therefore, are not routinely performed on C. difficile.

Metronidazole is well absorbed after oral administration and is excreted through the biliary tract before reaching the colon. Common adverse reactions include nausea, vomiting, diarrhea, dizziness, confusion, and an unpleasant metallic taste.[154] A disulfiram-like reaction can occur when alcohol or alcohol-containing medications are taken concurrently with metronidazole.[164] Because metronidazole is a carcinogen and, in some animal species, a mutagen, it should be used in pregnancy only if clearly needed. Similarly, metronidazole's safety in children has not been proved, and many prefer not to use it in this population if other options exist.[154]

Oral vancomycin produces fecal concentrations that are several 100 times the concentration needed to inhibit toxin-producing strains of C. difficile.[161] A 10 to 14-day course of oral vancomycin (125–500 mg orally 4 times daily) is recommended for the treatment of CDI, with all dosing regimens equally effective in the patients studied.[154],[161],[165],[166] Because of equal efficacy and high concentrations in the colon with all doses, vancomycin 125 mg is the most commonly prescribed dose. Although oral vancomycin is not well absorbed, measurable serum concentrations have been found in patients with both normal and compromised renal function, though higher and longer dose regimens, severe infection, and renal dysfunction were more associated with serum concentrations.[167]

Fidaxomicin is the newest antimicrobial indicated for the treatment of CDI.[168],[169] Fidaxomicin is a macrocyclic antibiotic active against C. difficile that is poorly absorbed and achieves high colonic concentrations.[170] It has limited antimicrobial spectrum and largely preserves colonic flora. In the primary clinical trial, patient outcomes on initial infection were similar when compared with vancomycin.[169] This finding, along with a significantly higher cost of therapy, has led many clinicians to suggest fidaxomicin be reserved as second-line therapy.[150],[171] However, one potential advantage for fidaxomicin was in recurrence rates, which were found to be significantly lower with fidaxomicin compared to vancomycin (15.4% vs. 25.3%, P = 0.005). While recurrence is a concern in CDI treatment, it is not yet clear if it is possible to identify patients for whom the higher cost would provide an additional benefit from this effect.

Table 69-5

Clostridium difficile Infection Severity of Disease

	Published guidelines	
Severity	Am J Gastroenterology 2013	SHEA/ISDA 2010
Mild-to-moderate	Diarrhea plus signs and symptoms that do not meet severe or complicated criteria	White blood count ≤15,000 cells/mL AND Serum creatinine <1.5× baseline
Severe	Serum albumin <3 g/dL PLUS either white blood count ≥15,000 cells/mL or Abdominal tenderness	White blood count >15,000 cells/mL OR Serum creatinine ≥1.5× baseline
Severe-to-complicated	Admission to intensive care unit Hypotension Fever ≥38.5°C Ileus or significant distension Mental status changes White blood count ≥35,000 or <2,000 cells/mL Serum lactate >2.2 mmol/L End organ failure	Hypotension or shock, ileus, megacolon

Source: Cohen SH et al. Society for Healthcare Epidemiology of America; Infectious Diseases Society of America. Clinical practice guidelines for Clostridium difficile infection in adults: 2010 Update by the Society for Healthcare Epidemiology of America (SHEA) and the Infectious Diseases Society of America (IDSA). Infect Control Hosp Epidemiol. 2010;31:431; Surawicz CM et al. Guidelines for diagnosis, treatment, and prevention of Clostridium difficile infections. Am J Gastroenterol. 2013;108:478.

Because B.W. is not critically ill, metronidazole (500 mg orally 3 times daily) for

10 to 14 days is recommended as first-line treatment.[157–159] Oral metronidazole and oral vancomycin are generally considered equally efficacious in mild-to-moderate disease,[158] but vancomycin use should be limited to prevent emergence of vancomycin-resistant organisms.[172] In addition, oral vancomycin capsules are significantly more expensive than a course of oral metronidazole. Some of this cost differential can be offset by using the IV vancomycin preparation to prepare an oral solution which can be flavored and prepared as directed in the package insert.

Once therapy directed against C. difficile is initiated, diarrhea or cramping should subside within 2 to 4 days. If B.W.'s symptoms have not resolved, vancomycin can be tried.[152]

ALTERNATIVE THERAPIES

Toxin Binders

Traditional anion-binding resins (e.g., cholestyramine, colestipol) are not as reliable or as rapidly effective as oral metronidazole or vancomycin and are not recommended as routine therapy.[173]

Probiotics

Using probiotics introduces probiotic microorganisms into the normal flora to counteract disturbances and reduce the colonization with pathogenic species.[174] Although orally administered, Lactobacillus species and the yeast Saccharomyces boulardii have been used to treat CDI, no data support the use of probiotics alone. Adjunctive use has been suggested to prevent CDI and its recurrences. A hospital trial looking at prevention of all ADD with Lactobacillus reported positive results for the prevention of CDI.[175] The results of that study, however, are tempered by the methodological exclusion of patients receiving antibiotics with a high risk of causing CDI, making generalization to other patient groups difficult. The exact role of probiotics in treatment or prevention of CDI is not yet known.[150],[171] Adding further caution to the widespread use of probiotics, reports of isolated adverse effects, including fungemia, with ingestion of viable S. boulardii have been reported.[158],[176]

Antidiarrheals

CASE 69-17, QUESTION 7: Should B.W. be given any antidiarrheal agent to relieve her symptoms?

Opiates and other antiperistaltic agents should be avoided in patients with CDI. Although these types of drugs may relieve diarrheal symptoms, they may also delay toxin removal from the GI tract. Evidence supporting these negative effects is minimal as data are scarce,[9] but caution would suggest avoiding any antimotilty agent in B.W.

CASE 69-17, QUESTION 8: Following resolution of B.W.'s CDI, is it necessary to send a follow-up stool sample to determine whether it is negative for C. difficile toxin?

After resolution of diarrhea, obtaining a follow-up stool sample to determine whether it is negative for C. difficile toxin is not recommended as part of routine practice because most patients with positive tests will not develop a recurrence of their diarrhea.[158] In addition, up to 3% of healthy adults carry small numbers of C. difficile in their feces, whereas colonization rates are much higher (31%–37%) in hospitalized patients and infants under 1 month.[177],[178]

Transmission

CASE 69-18

QUESTION 1: H.T., a 76-year-old man with multiple medical conditions, is admitted to the same 10-bed hospital ward as B.W. H.T.'s medical history is significant for a stroke that has left him bedridden in a nursing home. His only medications are those used to manage his hypertension. On day 4 of his hospitalization, H.T. complained of severe abdominal pain and watery, loose stools with blood. Physical examination revealed an ill-appearing man with a temperature of 101°F and hypotension. His WBC is 21,000 cells/mL. A stool specimen is positive for C. difficile toxin, and colonoscopy reveals pseudomembranes and colitis. A surgical consultant is considering an emergent colectomy because of possible bowel perforation secondary to the CDI. What are H.T.'s risk factors for acquiring C. difficile–associated pseudomembranous colitis during his hospitalization?

H.T.'s risk factors for acquiring CDI include his advanced age, bedridden status,[179] underlying diseases,[180] and admission to the hospital. CDI is spread when hospital personnel or equipment contaminated with C. difficile spores come into contact with susceptible patients. Physical proximity to an infected patient has been associated with an increased risk of CDI.[181] Therefore, measures to prevent the spread of CDI include hand disinfection before and after contact with infected patients; the use of gloves and gowns; enteric isolation precautions; and proper hand washing with soap and water (to remove any potential spores) after contact with infected patients with CDI. Contaminated equipment should be properly disinfected.[182]

Although C. difficile is often thought of as a nosocomial pathogen, it is being increasingly isolated in outpatient settings.[141],[183] This changing epidemiology has led to a standard definition of community-associated CDI in patients without any healthcare facility exposure within the last 12 weeks.[162] While many community-associated CDI infections appear in patients without antimicrobial exposure, antimicrobial use remains the highest risk factor.[184] Although proton-pump therapy and other acid suppression has been increasingly suspected as a cause of these infections, a meta-analysis of community-associated CDI did not find acid suppression to be a significant risk; however, corticosteroid use was associated with the disease.[184]

CASE 69-18, QUESTION 2: Over the next few days, all 10 patients on the ward with B.W. and H.T. are found to have C. difficile toxin in their stools. Five patients have diarrhea and the other five are asymptomatic. What is the role of antibiotic therapy directed at C. difficile in controlling this outbreak?

Neither oral metronidazole nor vancomycin is reliably effective in eradicating the carrier state (i.e., asymptomatic fecal excretion), and neither is recommended for use in this situation.[185] The lack of efficacy of these drugs is probably because of the fact that, unlike the vegetative forms of C. difficile, the spores of C. difficile are resistant to the action of antibiotics.[182] Furthermore, compared with placebo, vancomycin administration is associated with a significantly higher rate of C. difficile carriage 2 months after treatment.[185]

Controlling overall antibiotic use in the hospital can be a useful strategy. Antimicrobial stewardship is increasingly seen as a major control mechanism for CDI.[150] Restricting the use of single agents like clindamycin can be an effective component in efforts to control nosocomial epidemics of CDI.[179] With the emergence of the BI/NAP1 strain, control of all antibiotic use, especially fluoroquinolones, may be important in outbreak control.[186]

Finally, the overuse of acid suppressive therapy in the hospital setting, particularly proton-pump inhibitors, has been linked with increases in CDI.[187] Efforts to control use of these drugs have been increasingly recommended.[188]

CASE 69-18, QUESTION 3: What effect will the current CDI outbreak have on the outcomes of the infected patients and on health care costs?

In a prospective study, hospitalized patients who developed CDI had a 3.6-day increase in length of stay.[189] A large retrospective cohort study in the Veterans Affairs Administration reported a 2.3-day increase in hospitalization, with an increase of 4.4 days with severe disease.[190] A review of available economic data suggests additional hospital costs of $8900 to $30,000 for each case of CDI.[191] The current outbreak on the hospital ward is likely to increase both hospital costs and individual lengths of stay.

Severe C. difficile Infection

CASE 69-18, QUESTION 4: What treatment is recommended for H.T. who is critically ill from a CDI? What criteria should be used to characterize patients as “critically ill”?

Up to 57% of patients with antibiotic-associated pseudomembranous colitis who require surgical intervention (colectomy) die.[192] Although the precise definition of “critically ill” is not clear, it has variably included patients with pseudomembranes, age over 60, serum albumin <2.5 mg/dL, fever >38.3°C, severe abdominal pain, and marked leukocytosis (greater than 15,000–20,000 cells/mL).[146],[193] Recent guidelines from the Society for Healthcare Epidemiology of America and the Infectious Disease Society of America have suggested the definition of severity as presence of any of either of the following two parameters: white blood cell count ≥15,000 cells/mL or serum creatinine 1.5 times baseline[158] (See Table 69-5). Growing evidence suggests that vancomycin 125 mg orally 4 times daily may be more effective than metronidazole in patients with predefined severe disease.[158],[193] An additional definition of "severe, complicated" disease has been suggested for patients like H.T., who have hypotension, shock, ileus, or megacolon. The recommended therapy for H.T. would be a combination of vancomycin 500 mg orally 4 times daily and metronidazole 500 mg intravenously every 8 hours.[158] This combination therapy was shown to reduce mortality from 36.4% to 15.9% when compared with monotherapy in a small observational study.[194] The combination of high-dose therapies is theorized to overcome the difficulties for either medication to get to the site of action in the colon.

NON-ORAL TREATMENT

CASE 69-18, QUESTION 5: Three days after oral vancomycin and intravenous metronidazole is initiated, H.T. develops an ileus and cannot take anything by mouth. What therapeutic options are available to treat H.T.'s pseudomembranous colitis?

Adequate antibiotic levels in the colon are necessary to treat C. difficile–associated pseudomembranous colitis. If the oral route is not feasible (e.g., patients with an ileus or bowel obstruction), the clinician must choose an agent that is either secreted or excreted into the GI tract in its active form. IV vancomycin is not a desirable agent in this situation because it is not secreted into the GI tract. In contrast, intravenous metronidazole is eliminated by both renal and hepatic routes, and bactericidal concentrations are achieved in both serum and bile.[195]

The literature contains few reports of successful attempts to treat CDI or pseudomembranous colitis with IV metronidazole (500 mg q6–8h) alone.[196–198] Likewise, unsuccessful attempts to treat CDI with IV metronidazole have been reported.[196],[199] The clinical response of CDI to PO vancomycin in a patient who did not survive was difficult to ascertain.[161]

In adults, enteral vancomycin 500 mg 4 times daily can be given through an ileostomy or colostomy (if present). Several reports of successful outcomes using intracolonic vancomycin (as an adjunct to oral or IV antibiotics) in patients with CDI have been documented. Rectal doses of vancomycin have varied from 500 mg q4–8h to 1,000 mg/L q8h.[200] Rectal vancomycin administration volumes of 500 mL are suggested to better ensure delivery to the transverse and distal colon.[150] Saline can be used as a carrier, but electrolytes should be monitored because absorption can occur. Lactated Ringer's solution may be preferred if hyperchloremia is present.[150]

Because patients with CDI are at risk for colonic perforation, enteral vancomycin should be administered cautiously.

Relapse

CASE 69-19

QUESTION 1: P.V. is a 57-year-old male who acquired CDI on the same ward as the other infected patients. P.V. was treated with metronidazole 500 mg orally 3 times daily for 10 days while in the hospital. One week after discharge from the hospital, P.V. once again developed abdominal pain and diarrhea. His clinic physician assumed these symptoms could not be related to a relapse of his CDI because he had responded so well to metronidazole. What is the likelihood that CDI has recurred?

Regardless of the antibiotic regimen prescribed for CDI, symptomatic relapse occurs in 5% to 30% of patients who respond to their initial treatment regimen.[155],[182] Relapses occur 2 weeks to 2 months (median of 7 days) after treatment has been discontinued.[201] In most instances, relapses are caused by germination of dormant spores that are intrinsically resistant to antibiotics. Reinfection with C. difficile from external sources, however, may account for up to half of all second episodes.[202] In rare instances, either vancomycin[203] or metronidazole[204] may have caused CDI.

Risk factors for recurrent CDI include increasing age (≥65 years), use of proton-pump inhibitors, renal insufficiency, continued use of antimicrobials during CDI treatment, and glucocorticoid use.[205],[206]

Data suggest that patients with a poor immune response to C. difficile toxin A are more likely to have a relapse of CDI.[207] It is not clinically helpful in the case of P.V., because no standard tests are currently available for this immune response. The influence of the immune system, however, has led to the usage of IV immune globulin in refractory or severe cases of CDI.[208],[209] The utility of the usage of immune globulins has been debated in small single institution reviews. Immune globulins would not be the considered the next line of therapy for P.V.

CASE 69-19, QUESTION 2: How should P.V.'s CDI relapse be treated?

Most infections resulting from relapse are not related to bacterial resistance and they respond to retreatment with the same antibiotic used for initial treatment of the CDI.[155],[210] Thus, an appropriate approach for P.V. is to administer another 10 to 14-day course of oral metronidazole.

For patients with multiple recurrences of CDI, the optimal management plan is unresolved.[182] Different approaches have been tried, including (a) high-dose oral vancomycin

---

(2,000 mg/day)[211]; (b) a 4- to 6-week course with vancomycin, after which the dose is tapered over a 1- to 2-month period[211],[212]; (c) exchange resins[213],[214] with or without antibacterials; (d) "pulse" dosing of vancomycin every 2 to 3 days[211]; or (e) a combination of vancomycin and rifampin (600 mg orally twice daily).[215] Tapered and pulse therapy with vancomycin were shown to be most effective in a clinical trial comparing multiple strategies.[211] When combined with standard antibiotic therapy, a clinical trial with the probiotic S. boulardii for cases of relapsing CDI noted a 65% response rate versus a 36% response rate for combination therapy with placebo.[216] The relapse rate was reduced to 17% when S. boulardii was combined with high-dose vancomycin.[217]

Following treatment with vancomycin, a "chaser" course of rifaximin, a poorly absorbed rifamycin derivative, was successful in separate case series for patients with multiple relapses.[218],[219] Concern must be raised that the single failure occurred in concert with emerging rifaximin resistance.[218]

Because of its more minimal impact on fecal flora, fidaxomicin may be recommended for recurrent infections, although there is less evidence for its use in recurrence compared to other recommended agents.[171] Fidaxomicin's inherent advantage in limiting recurrence with initial treatment and treatment of first recurrences may lie in cost savings.[220],[221]

Finally, fecal microbiota transplant (FMT) therapy has been more widely investigated in second and third relapses and has shown significant promise.[222] Healthy fecal donors, often family members, are the usual source for fecal microbiota, though frozen "banks" of FMT samples have been increasing.[223] Administration of FMT can be provided through nasogastric or nasojejeunal tubes, colonoscopy, or colonic enemas. Although published data overall remain small, a systematic review of the literature supports the efficacy (85% cure rates) and limited adverse effects of this therapy.[222] Long-term follow-up from a multi-center study of 17 patients found 88% to 94% success rates.[224] A single cost-effectiveness model, using literature-based data, found FMT to be more cost-effective compared to treatment of recurrences with vancomycin.[224]

Intra-Abdominal Infections

Sheila K. Wang and Carrie A. Sincak

CORE PRINCIPLES	CHAPTER CASES
① Acute cholecystitis is the acute inflammation of the gallbladder, presenting with fever, prolonged abdominal pain, and positive Murphy's sign of the right upper quadrant followed by nausea and vomiting. Acute cholangitis is an acute inflammation of the common bile duct with accompanying classic Charcot's triad: fever, jaundice, and right upper quadrant pain.	**Case 70-1 (Question 1)**
② Empiric therapy for severe biliary tract infections may include combination therapy with either ciprofloxacin, levofloxacin, or cefepime plus metronidazole or monotherapy with piperacillin/tazobactam or an antipseudomonal carbapenem (imipenem/cilastatin, meropenem, doripenem) if multidrug-resistant gram-negative rods are suspected.	**Case 70-1 (Question 3)**
③ Spontaneous bacterial peritonitis (SBP) is largely a monomicrobial infection commonly caused by aerobic enteric gram-negative rods, such as Escherichia coli and Klebsiella pneumoniae.	**Case 70-2 (Question 1)**
④ Empiric therapy for SBP may include a third-generation cephalosporin such as ceftriaxone or cefotaxime or parenteral fluoroquinolone with activity versus Streptococcus pneumoniae. Length of therapy depends on the reduction of polymorphonuclear leukocyte counts (<250 cells/μL) in peritoneal fluid, generally occurring in 5 days or fewer.	**Case 70-2 (Question 2)**
⑤ For secondary peritonitis, empiric antimicrobial therapy for community-acquired infections is routinely initiated without obtaining Gram stain and culture. Blood cultures may be useful, however, in health care–associated infections for detection of gram-positive cocci, yeast, or multidrug-resistant pathogens.	**Case 70-4 (Question 2)**
⑥ Therapy for secondary peritonitis should include antimicrobial coverage directed at gram-negative bacteria and anaerobes. Therapy may include (a) certain extended-spectrum β-lactams or β-lactamase inhibitor combinations, (b) carbapenems, or (c) a fluoroquinolone with metronidazole.	**Case 70-4 (Question 3)**
⑦ Duration of therapy for intra-abdominal infections typically ranges from 4 to 7 days. Clinical response and source control influence duration of therapy.	**Case 70-4 (Question 4)**
Acute penetrating abdominal trauma requires a short course (<24 hours)	**Case 70-7 (Question 2)**

8 of antimicrobial therapy. Delay of therapy or development of infection necessitates a 5 to 7-day course of therapy.

INTRODUCTION

Despite the introduction of new antimicrobial agents and improvements in diagnostic and surgical techniques, the treatment of intra-abdominal infections remains a therapeutic challenge. However, advances in radiographic and interventional techniques with timely source control, improved fluid and nutritional management, and the selection of appropriate antimicrobial agents have decreased mortality in intra-abdominal infections.[1]

Intra-abdominal infections are those contained within the peritoneal cavity, which extends from the undersurface of the diaphragm to the floor of the pelvis or the retroperitoneal space. Intra-abdominal infections can present as a localized infection (e.g., appendicitis), a diffuse inflammation throughout the peritoneum (peritonitis), or as abscesses, which can form

anywhere within the abdomen, between bowel loops, or in solid organs such as the liver, biliary tract, spleen, pancreas, or female pelvic organs.

Empiric antimicrobial therapy should be initiated as soon as an intra-abdominal infection is suspected. Therapy should be selected on the basis of the suspected pathogens; however, antimicrobial therapy alone is insufficient, especially in the setting of diffuse peritonitis. Source control is a term used to involve all physical measures needed to eradicate an infection, such as debridement of necrotic tissue or drainage of an abscess or fluid collection. If adequate source control is delayed, bacteremia, multiple organ failure, and mortality are more likely to occur.[2]

Normal Gastrointestinal Flora

The stomach of fasting individuals contains very few bacteria (i.e., <100 colony-forming units [CFU]/mL) as a result of gastric motility and the bactericidal activity of normal acidic gastric fluid.[1] The bacterial population of the stomach can be altered by drugs or diseases that increase gastric pH or decrease gastric motility. Not surprisingly, patients with bleeding or obstructing duodenal ulcers, gastric ulcers, gastric carcinomas, or those receiving proton pump inhibitors or histamine-2 receptor antagonists have an increased number of oral bacteria colonizing the stomach.

The upper small intestine (duodenum and jejunum) usually contains relatively few bacteria and harbors mainly oral flora. The lower small intestine serves as a transitional zone between the sparsely populated stomach and the abundant microbial flora of the colon.[3],[4]

In the ileum, facultative gram-negative and gram-positive species, as well as obligate anaerobes, are encountered. As the distal ileum is approached, the quantity and variety of bacteria increase. Substantial numbers of anaerobic bacteria are present, including Bacteroides species, as well as Escherichia coli and Enterococcus species.[1],[3]

In the large bowel, anaerobic bacteria, particularly Bacteroides species, predominate. In the distal colon, bacterial counts average 10^{10} CFU/mL of feces, with anaerobes outnumbering other organisms by a ratio of 1,000 to 10,000:1.[3] Among the facultative aerobes, E. coli is the most frequently isolated species.[1],[3] Given these differences in regional microflora populations, it is not surprising that trauma to the colon carries a much higher risk of intra-abdominal infection in comparison with the stomach or jejunum[5] (Fig. 70-1; Table 70-1).

Resistant flora are more common in health care–associated infections, including Pseudomonas aeruginosa, Acinetobacter species, extended-spectrum β-lactamases (ESBLs) and carbapenemase producing E. coli and Klebsiella species, methicillin-resistant Staphylococcus aureus (MRSA), enterococci, and Candida species.[6–10]

Common Pathogens in Intra-Abdominal Infection

Disease	Common Pathogens	Comments
Cholecystitis, cholangitis	E. coli, Klebsiella pneumoniae, Enterococcus, and anaerobes	Enterococcus species and anaerobes are less frequently isolated, but they have been associated with nosocomial infections and chronic surgical infections, particularly in patients receiving broad-spectrum antimicrobials.
Primary peritonitis	E. coli, K. pneumoniae, Streptococcus pneumoniae, occasional anaerobes	Also known as spontaneous bacterial peritonitis presented in cirrhotic patients. Often

		monomicrobial. Anaerobes less likely than aerobes.
Secondary peritonitis	E. coli, Bacteroides fragilis, Enterococcus, and anaerobes	Generally polymicrobial with both aerobic and anaerobic pathogens. Enterococcus species should be considered in the setting of health care–associated infections.
Chronic ambulatory peritoneal dialysis	Staphylococcus epidermidis, Staphylococcus aureus, diphtheroids, gram-negative rods	Dwell time of exchange with intraperitoneal antibiotics must be a minimum of 6 hours.

INFECTIONS OF THE BILIARY TRACT

Cholecystitis and Cholangitis

Cholecystitis and cholangitis originate as inflammatory conditions, usually as a result of obstruction in the gallbladder or common bile duct. The obstruction is typically caused by the presence of stones. The biliary tract is sterile under normal conditions, and the flow of bile, along with its bacteriostatic properties, functions to maintain the sterility. Infection typically occurs as a secondary event to obstruction.[4,5]

Acute cholecystitis is the acute inflammation of the gallbladder. The presence of gallstones in greater than 90% of cases prevents the outflow of gallbladder drainage by obstructing the neck of the gallbladder, Hartmann's pouch, or the cystic duct.[4] The obstruction causes an increase in intraluminal pressure, gallbladder distension, and edema, which triggers an acute inflammatory response. The potential consequences of this obstruction and inflammation include infection, ischemia, perforation, and necrosis.[4,11] The reduction in gallbladder outflow leads to biliary stasis, which provides an ideal environment for bacterial proliferation and subsequent infection (Fig. 70-2).

Acute cholangitis is an acute inflammation of the common bile duct. The most common cause of cholangitis in the United States is common bile duct obstruction as a consequence of choledocholithiasis. Less common causes include neoplastic obstruction, postoperative obstruction after biliary intervention, benign strictures, and primary sclerosing cholangitis.[4] The decrease in biliary outflow results in biliary stasis and bacterial proliferation. Infection results in a rapid rise in biliary pressure, which facilitates the spread of bacteria into lymphatics and the bloodstream via alterations in membrane permeability. In comparison with cholecystitis, acute cholangitis generally carries a poorer prognosis.[4,12]

CLINICAL PRESENTATION AND DIAGNOSIS

CASE 70-1

QUESTION 1: D.S., a 54-year-old man, presents to the hospital with a 1-week history of abdominal pain and tenderness, localized to the right upper quadrant, fever of 38.9°C, and chills. He complains of nausea, with three episodes of emesis occurring in the past 24 hours. D.S. appears jaundiced and reports dark-colored urine. His laboratory values are the following:

White blood cell (WBC) count, $17 \times 10^3/\mu L$
Serum creatinine (SCr), 1.1 mg/dL
Total bilirubin, 6 mg/dL
Alkaline phosphatase, 270 U/L

What evidence of cholangitis exists in D.S.? How does the presentation of cholecystitis differ from cholangitis?

The clinical manifestations of acute cholangitis vary, but the classic presentation involves Charcot's triad, which consists of fever, jaundice, and right upper quadrant abdominal pain. Fever is present in 90% of cases, and jaundice and abdominal pain occur in 60% to 70% of cases.[4] A smaller percentage of patients, generally with gram-negative septicemia, may present with changes in mental status and hypotension.[4] Laboratory findings of acute cholangitis include leukocytosis, elevated bilirubin (>2 mg/dL), and alkaline phosphatase, and mildly elevated liver transaminases.[4],[13] The clinical signs and symptoms of cholangitis, as exemplified by D.S., include high fevers (38.9°C), chills, jaundice, and right upper quadrant abdominal pain. Laboratory evidence supportive of cholangitis includes leukocytosis with WBC of 17 × $10^3/\mu L$, increased bilirubin of 6 mg/dL, and elevated alkaline phosphatase of 270 U/L.

The clinical presentation of acute cholecystitis involves fever and prolonged constant abdominal pain typically localized to the right upper quadrant, followed by nausea and vomiting. On physical examination, tenderness in the right upper quadrant and a positive Murphy's sign (inspiration is inhibited by pain on palpation) are often present.[4],[11] Laboratory findings include leukocytosis with increased neutrophils (left shift) and mild elevations in transaminases. Jaundice is less common in patients with cholecystitis (bilirubin <4 mg/dL) compared with cholangitis.[4],[11]

Diagnostic imaging for acute cholecystitis and cholangitis involves ultrasonography. Findings for acute cholecystitis may reveal pericholecystic fluid, distension of the gallbladder, thickening of the gallbladder wall, stones, and a sonographic Murphy's sign.[14] Ultrasound is less sensitive for choledocholithiasis, but it may reveal biliary dilation with stones. Hepatobiliary scintigraphy is another diagnostic tool used to identify obstruction of the cystic duct. After intravenous injection with technetium hepatobiliary iminodiacetic acid (Tc-HIDA), failure to observe gallbladder filling suggests acute cholecystitis.[6],[14] Computed tomography (CT) imaging may be superior in determining the extent of biliary obstruction.[4] Endoscopic retrograde cholangiopancreatography (ERCP) is an alternative mode of imaging for cholangitis.[4],[13]

ETIOLOGY

CASE 70-1, QUESTION 2: What are the most likely organisms causing infection in D.S.? What clinical specimens are helpful to identify the causative pathogen(s)?

The most common pathogens associated with acute cholangitis include E. coli, Klebsiella species, and Enterobacter species. However, P. aeruginosa, skin flora (Staphylococcus species, Streptococcus species), and oropharynx bacteria may be implicated. Anaerobic organisms, commonly Bacteroides species, are associated with approximately 15% of infections, particularly in elderly patients undergoing biliary tract surgery.[4],[15] The etiology of cholecystitis typically involves E. coli, Klebsiella species, and Enterococcus species. Anaerobes are less commonly isolated (Table 70-1).[4],[11]

As described above, the stasis of bile flow results in proliferation of bacteria within the gallbladder or common bile duct. Acute cholangitis results in increased pressure within the common bile duct with dissemination of bacteria from the biliary tree to the bloodstream. Blood cultures may be positive in up to 40% of patients with symptomatic acute cholangitis.[4] Acute cholecystitis may reveal positive bile cultures in 20% to 75% of patients with symptomatic disease, but the utility of bile cultures has yet to be determined.[3] In contrast to cholangitis, bacteremia is unlikely with cholecystitis. The choice of antibacterial agents is largely empiric covering the aforementioned common causative pathogens.

TREATMENT

Definitive therapy for both cholangitis and cholecystitis must involve source control, using surgery, percutaneous drainage, or endoscopic intervention. Empiric antibacterial therapy should be added owing to the likelihood of secondary infection and to prevent complications. Supportive measures include fluid and electrolyte supplementation and analgesia.[4],[5],[11],[13]

To decompress or drain the biliary ductal system in cholangitis, ERCP is used with a success rate of greater than 90% in the treatment of cholangitis.[4] Alternatively, percutaneous transhepatic biliary drainage or endoscopic sphincterotomy can be used to drain the contents. Open surgery is a less favored option to decompress the biliary tree as it is associated with increased mortality.[4] Acute symptomatic cholecystitis requires removal of the gallbladder (cholecystectomy). The procedure of choice is laparoscopic cholecystectomy within 48 to 72 hours of onset of symptoms. Early intervention is associated with decreased morbidity and length of hospital stay compared with delayed surgical intervention.[4],[11] In high-risk patients, in whom the risks outweigh the benefits of early surgery, percutaneous cholecystostomy can be performed to drain the contents of the gallbladder. The procedure improves the clinical symptoms in 75% to 90% of patients who cannot undergo surgery. Cholecystectomy, however, should take place once the patient is stable enough for surgery.[4]

ETIOLOGY

CASE 70-1, QUESTION 3: Based on the most likely causative pathogen(s), what empiric antimicrobial therapy is recommended for D.S., given a diagnosis of cholangitis?

Empiric antimicrobial therapy for acute cholangitis and cholecystitis should be initiated after blood cultures have been collected. The empiric choice of therapy should cover enteric gram-negative pathogens, particularly E. coli (Table 70-2).[5],[6] In general, the addition of anaerobic coverage is not mandatory for cholecystitis; however, it should be considered in the setting of severe cases such as acute cholangitis, biliary-enteric anastomosis, or health care–associated infections.[6] Empiric coverage for Enterococcus species should be considered for patients at risk for health care–associated infections, such as immunocompromised patients, patients who have required long-term hospitalization, patients who have received broad-spectrum antimicrobial therapy, or patients with valvular heart disease or prosthetic intravascular materials.[6] Antimicrobial therapy must be guided by drug pharmacokinetics and pharmacodynamics, local resistance patterns, and patient factors, such as drug allergies, renal or hepatic dysfunction, and cost.

Considering their activity versus multidrug-resistant gram-negative bacilli, carbapenems generally should be reserved for infection caused by these pathogens. Vancomycin may be added empirically in health care–associated biliary infections in which ampicillin-resistant enterococci and MRSA are of concern. Linezolid or daptomycin may be considered in cases of known vancomycin-resistant Enterococcus species (VRE). Empiric broad-spectrum antimicrobial regimens should be narrowed, when possible, based on culture and susceptibility findings. For mild-to-moderate community-acquired acute cholecystitis, monotherapy with cefazolin, cefuroxime, or ceftriaxone is recommended. Because of a wide prevalence of ampicillin–sulbactam resistant E. coli, this agent is no longer recommended for empiric use.[6],[15] Resistance to fluoroquinolones is problematic with unpredictable susceptibility of E. coli to ciprofloxacin and levofloxacin.[16] Current guidelines for complicated intra-abdominal infections (cIAI) suggest fluoroquinolones be considered for therapy when institutional antibiograms indicate greater than 90% susceptibility of E. coli.[6] Use of aminoglycosides is not routinely recommended because of the need for therapeutic drug monitoring and potential nephrotoxicity and ototoxicity.[6] Furthermore, in comparison with other regimens, aminoglycoside-based regimens are inferior in the treatment of intra-abdominal infections.[17] However, some argue the decreased efficacy of aminoglycosides has been caused by inadequate dosing. An appropriate empiric regimen for D.S. would be piperacillin–tazobactam 3.375 g intravenously (IV) every 6 hours.

Table 70-2

Treatment Options for Intra-Abdominal Infections[5,6,66,67]

Infection	Agents and Regimens	Agent Dosing[d]
Mild-to-moderate in severity: Community-acquired perforated or abscessed appendicitis Or Acute cholecystitis	**Single agent** Cefoxitin Ertapenem Moxifloxacin[a] Tigecycline **Combination** Cefazolin Or Ceftriaxone Or Cefotaxime Or Ciprofloxacin Or Levofloxacin[a] + Metronidazole	Cefoxitin 2 g IV every 6 hours Ertapenem 1 g IV every 24 hours Tigecycline 100 mg initially then 50 mg IV every 12 hours Cefazolin 1–2 g IV every 8 hours Ceftriaxone 1–2 g IV every 12–24 hours Cefotaxime 1–2 g IV every 6–8 hours Ciprofloxacin 400 mg IV every 12 hours Levofloxacin 750 mg IV every 24 hours Moxifloxacin 400 mg IV every 24 hours Metronidazole 500 mg IV every 8–

High risk in severity: Community-acquired acute cholecystitis with severe physiologic disturbance, advanced age, or immunocompromised state Or Acute cholangitis associated with biliary-enteric anastomosis Or Health care–associated intra-abdominal infections	**Single agent** Imipenem–cilastatin Meropenem Doripenem Piperacillin–tazobactam **Combination** Cefepime Or Ceftazidime Or Ciprofloxacin Or Levofloxacin[a] + Metronidazole	12 hours Cefepime 1-2 g IV every 8 hours and Ceftazidime 1-2 g IV every 8-12 hours Piperacillin–tazobactam 3.375 g IV every 4–6 hours or 4.5 g IV every 6 hours[e] Imipenem–cilastatin 500 mg IV every 6 hours or 1 g every 8 hours Meropenem 1 g IV every 8 hours Doripenem 500 mg IV every 8 hours Vancomycin[b] 15–20 mg/kg IV every 8–12 hours (normal renal function) Aztreonam[c] 1–2 g IV every 6–8 hours Ceftazidime/avibactam 2.5 g IV every 8 hours or Ceftolozane/tazobactam 1.5 g IV every 8 hours + Metronidazole 500 mg IV every 8–12 hours

[a] Selection of fluoroquinolones should be based on local antibiogram or susceptibility reports.

[b] May be added to each regimen in the setting of health care–associated intra-abdominal infections (e.g., methicillin-resistant Staphylococcus aureus or ampicillin-resistant enterococcal infection).

[c] For patients who are intolerant of β-lactams, aztreonam may be considered as an alternative agent for gram-negative coverage.

[d] normal renal function dosing

[e] Extended infusion: 3.375 g IV every 8 hours over 4 hours

IV, intravenous.

BILIARY CONCENTRATIONS

CASE 70-1, QUESTION 4: The physician caring for D.S. questions the need for an antibiotic that concentrates in the bile. Is there a benefit to using an antibiotic that is extensively excreted into bile?

Common bile duct obstruction prevents the entry of antibiotics into the bile, and the need for high biliary concentrations of antibiotics in the treatment of cholangitis has been debated.[18] Nagar and Berger[19] concluded that a number of antibiotics with excellent in-vitro susceptibility, but poor biliary excretion, are still clinically effective. Biliary antibacterial concentrations do not correlate with an improved clinical outcome.[4] Highly biliary-excreted versus moderately biliary-excreted antibiotics have been compared.[18] Serum concentrations are more important than biliary levels in reducing the septic complications of biliary tract surgery.

Furthermore, biliary excretion of any antibiotic is minimal in the presence of obstruction.[18]

The treatment of D.S.'s biliary tract infection must include biliary drainage. Piperacillin–tazobactam should be continued for 4 to 7 days.

PRIMARY PERITONITIS

Peritonitis is inflammation of the peritoneum as a result of infectious or chemical inflammation within the peritoneal cavity.[3,20] Infectious peritonitis can be classified as primary, secondary, or tertiary. Primary peritonitis involves the development of infection in the peritoneal cavity in the absence of intra-abdominal pathology.[20,21] Secondary peritonitis classically results from contamination of the peritoneum with gastrointestinal (GI) or genitourinary microorganisms as a result of the loss of mucosal barrier integrity. Tertiary peritonitis is clinical peritonitis along with signs of sepsis and multi-organ dysfunction persisting or recurring after the treatment of secondary peritonitis.[3,20]

Primary peritonitis is also known as spontaneous bacterial peritonitis (SBP) and is most frequently identified in adults with cirrhosis and ascites. Nearly 10% to 30% of hospitalized patients with cirrhosis and ascites have SBP.[3,21,22] Primary peritonitis is associated with post-necrotic cirrhosis, chronic acute hepatitis, acute viral hepatitis, congestive heart failure, metastatic malignancy, or systemic lupus erythematosus.[3,20]

Spontaneous Bacterial Peritonitis in Cirrhotic Patients

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with SBP may present with fever, signs of peritonitis, including abdominal pain, altered mental status, changes in GI motility, nausea, vomiting, diarrhea, or ileus.[22] Fever is common, occurring in 50% to 80% of patients.[3] Some patients have an atypical presentation or even lack symptoms.[22] The diagnosis of SBP is made on clinical presentation and examination of the peritoneal fluid via paracentesis. The ascitic fluid is tested for cell counts with WBC differential, and the presence of microorganisms is based on Gram stain and culture. Ascitic fluid with an elevated polymorphonuclear (PMN) count (≥250/µL) is diagnostic for SBP.[22]

ETIOLOGY AND PATHOGENESIS

CASE 70-2

QUESTION 1: M.W., a 51-year-old man with alcoholic cirrhosis and significant abdominal ascites, presents with a 4-day history of fever of 38.4°C and abdominal pain. Ascitic fluid obtained by paracentesis was cloudy, and culture of the ascitic fluid is pending. Laboratory values include ascitic fluid PMN count, 450/μL; serum WBC count, 12.2 × 10^3/μL; and total bilirubin, 4.4 mg/dL. What organisms are likely to be cultured from M.W.'s ascitic fluid?

An estimated 70% of cases of SBP are caused by aerobic enteric organisms considered normal flora of the GI tract.[22] E. coli is the most common pathogen, followed by K. pneumoniae.[3] Other common causes of SBP include Streptococcus pneumoniae and other Streptococcus species, accounting for 20% of cases. Enterococcus species are isolated in approximately 5% of cases.[22] Staphylococcus species, anaerobes, and microaerophilic organisms are rarely reported in community-acquired SBP. SBP is largely a monomicrobial infection.

One of the main mechanisms of pathogenesis associated with the development of SBP is bacterial translocation, which is the migration of microorganisms through the GI wall to mesenteric lymph nodes and other structures outside the intestine, including the bloodstream. Bacteria then infect the ascitic fluid by hematogenous or lymphogenous spread.[22],[23] Certain characteristics of cirrhotic patients facilitate the pathogenesis of SBP, including bacterial overgrowth, decreased motility, structural intestinal damage, and decreased host-defense mechanisms that normally function to eliminate microorganisms. Bacterial overgrowth in the face of decreased motility and increased gut wall permeability, secondary to structural damage, facilitates subsequent systemic infection. Reduced opsonic activity and phagocytosis allow the microorganisms to escape the hosts' defenses and subsequently infect the ascitic fluid.[23] SBP with underlying cirrhosis was previously associated with a greater than 90% mortality rate, but with the advances in antibacterial therapy the rate has been reduced to approximately 30% to 40%.[3],[22] Gram-negative pathogens are associated with increased mortality compared with gram-positive pathogens.[3] Early diagnosis and effective antibacterial treatment of SBP are associated with reduced rates of mortality.[24] Patient characteristics associated with increased mortality include renal insufficiency, hypothermia, hyperbilirubinemia, and hypoalbuminemia. To decrease the rate of renal dysfunction associated with SBP, intravenous albumin at 1.5 g/kg within 6 hours of diagnosis and 1 g/kg on day 3 may be administered. Albumin acts as a volume expander to lessen hemodynamic changes, thereby preserving renal function. Albumin is recommended in patients with a serum creatinine >1 mg/dL, blood urea nitrogen (BUN) >30 mg/dL, or total bilirubin >4 mg/dL.[22]

ANTIMICROBIAL THERAPY

CASE 70-2, QUESTION 2: Pending ascitic fluid culture results, what empiric antimicrobial therapy should be recommended for M.W.? What is an appropriate duration of therapy, and how should the response to therapy be monitored?

Although a positive Gram stain and culture guides antibacterial therapy, nearly

60% of patients with signs and symptoms of SBP have negative cultures.[3],[24] Initial antibacterial therapy for patients with a diagnosis of SBP is typically empiric and targeted toward the most likely pathogens as described previously. Ampicillin plus an aminoglycoside was the traditional choice for empiric therapy; however, third-generation cephalosporins (cefotaxime and ceftriaxone) represent safer, more-effective options.[25],[26] A fluoroquinolone may be considered an alternative in patients with β-lactam allergies. Levofloxacin and moxifloxacin are preferred over ciprofloxacin, because of their superior activity against S. pneumoniae, the most commonly isolated gram-positive bacterial pathogen. Although parenteral therapy is preferred, oral fluoroquinolones may be as effective in patients with uncomplicated SBP.[25] As described earlier, aminoglycosides are not recommended in cirrhotic SBP therapy because of the risk of nephrotoxicity, and the decision whether or not to use fluoroquinolones should be based on institutional antibiogram reports.[22]

Antibiotic therapy is recommended until the PMN count from the ascitic fluid falls below 250 cells/μL, which normally occurs within 5 days.[24] França et al.[27] concluded that a 5-day course of cefotaxime for the treatment of SBP was as effective as a 10-day course.

M.W. should receive empiric therapy with an antimicrobial agent effective against E. coli and other common pathogens such as Klebsiella species and S. pneumoniae. Any of the above-mentioned options would be reasonable empiric choices.

PROPHYLAXIS

CASE 70-2, QUESTION 3: After treatment is completed, should prophylactic antimicrobial therapy be initiated in M.W.?

Recurrence rates for SBP are high. Cirrhotic patients who survive an episode of SBP have a 1-year recurrence rate of nearly 70%. Antibiotic prophylaxis should be administered to the following patients since they are considered high risk for the development of SBP: patients who have had one or more episodes of SBP; cirrhotic patients with gastrointestinal bleeding; cirrhotic patients with ascites, who have impaired renal or liver function; or cirrhotic patients with a low ascitic protein (<1.0 g/dL) or elevated serum bilirubin (>2.5 mg/dL).[22]

Antibiotic prophylaxis in cirrhotic patients is typically initiated to provide selective decontamination of the GI tract. The goal of this therapy is to reduce the burden of bacteria and subsequently prevent bacterial translocation and infection.[22] Prospective, randomized studies in cirrhotic subjects with ascites support the use of oral antibacterial agents to reduce the rate of recurrence. The agents studied include oral norfloxacin,[28] ciprofloxacin,[29] and trimethoprim–sulfamethoxazole.[30] Rifaximin, a nonabsorbable derivative of rifamycin, has also been shown to significantly reduce the occurrence of SBP.[31] Long-term prophylaxis is recommended based on the significant reduction in rates of recurrence in clinical trials. Long-term prophylaxis in patients with low ascitic protein, elevated bilirubin, or both may also be beneficial, but it has not been associated with decreased overall infection or mortality and, therefore, is not uniformly recommended.[22],[23],[28–30] Clinical trials have provided evidence to support the use of short-course therapy (7 days) of norfloxacin (no longer available in the United States) or ceftriaxone in cirrhotic patients presenting with GI hemorrhage.[23],[32] Prophylactic therapy prevents bacterial infection and

---

reduces the risk of rebleeding.[23] Several cost analyses have been performed demonstrating that prophylactic therapy in high-risk groups of cirrhotic patients is cost-effective.[23]

Because rates of fluoroquinolone-resistant and trimethoprim–sulfamethoxazole–resistant organisms are more prevalent in patients who receive long-term prophylactic therapy, its long-term use must be considered when initiating antibacterial therapy for the treatment of new infections in this patient population.[33],[34]

M.W. has cirrhosis, a previous episode of SBP, and a high total bilirubin; thus, he is at high risk for recurrence. Prophylactic antimicrobial therapy should be considered and may be a cost-effective measure. M.W. would benefit from ciprofloxacin 500 mg PO daily. The use of trimethoprim–sulfamethoxazole would depend on local resistance patterns.

Continuous Ambulatory Peritoneal Dialysis–Associated Peritonitis

PATHOGENESIS AND CLINICAL PRESENTATION

CASE 70-3

QUESTION 1: H.M., a 33-year-old woman with HIV and end-stage renal disease, has undergone continuous ambulatory peritoneal dialysis (CAPD) daily for the past year. She presents with abdominal pain and a cloudy dialysate fluid. H.M. has negligible residual urine output. What are the most common causative organisms related to CAPD-associated peritonitis? What empiric antimicrobial therapy should be initiated? How should antimicrobial agents be administered?

Following SBP, peritoneal dialysis is another cause of primary peritonitis. An estimated 45% of patients undergoing CAPD will experience at least one episode of peritonitis in the first 6 months of dialysis. Approximately 60% to 70% of patients exhibit peritonitis during the first year of dialysis, and recurrent infection occurs in 20% to 30% of patients.[3] CAPD-associated peritonitis is theorized to originate from contamination of the catheter by organisms of the normal skin flora, contamination of the peritoneum from an exit-site or subcutaneous-tunnel infection, contamination of the dialysate fluid, or bacterial translocation.[3] Alterations in host defenses of the peritoneum may also have a role in the development of CAPD-associated peritonitis.[3]

Clinical manifestations of CAPD-associated peritonitis include abdominal pain and tenderness, which is observed in 60% to 80% of patients. Nausea and vomiting occur in approximately 30% of patients, whereas 10% will have diarrhea and 10% to 20% will present with fever. The diagnosis of peritonitis is made on the basis of clinical signs and symptoms along with examination of the dialysate fluid for cell counts, Gram stain, and culture. Characteristically, the dialysate fluid will be cloudy and have a WBC count greater than 100 cells/μL with a neutrophilic predominance (at least 50%).[35] The Gram stain may be negative in 5% to 10% of cases, and blood cultures are typically negative.[3] In most cases, peritonitis is commonly caused by a single organism.[36]

ETIOLOGY

The most common causative organisms are gram-positive bacteria, accounting for 60% to 80% of isolates. Coagulase-negative Staphylococcus species (S. epidermidis) are the most common causative organisms, followed by S. aureus and Streptococcus species. Gram-negative bacilli are isolated in approximately 15% to 30% of cases, with E. coli being the most common. Other common gram-negative organisms include Klebsiella species, Enterobacter species, Proteus species, and P. aeruginosa. Anaerobes, fungi, and mycobacteria constitute the less commonly encountered pathogens.[3]

ANTIMICROBIAL THERAPY

In general, empiric antibiotic therapy should be directed against the most common causative organisms, both gram-positive and gram-negative, until cultures of peritoneal fluid are available. Intraperitoneal (IP) delivery of antibacterial agents is the preferred route of administration for the treatment of CAPD-associated peritonitis. The IP route provides very high local concentrations of antibacterial agents as well as the ability to avoid a venipuncture and allow the patient to self-administer therapy at home.[35]

Empiric IP administration of antibiotics should be administered when CAPD-associated peritonitis is suspected. When culture and susceptibility results are available, antibacterial therapy should be adjusted as necessary. With appropriate therapy, a clinical response should be expected within the first 48 hours.[35]

Treatment guidelines for CAPD-associated peritonitis provide a systematic approach for antimicrobial selection, dosing guidelines, and duration of therapy. Initial IP therapy recommendations include vancomycin or a first-generation cephalosporin for gram-positive coverage plus an antibacterial agent with antipseudomonal coverage.[35] Because of the increasing rates of MRSA and methicillin-resistant S. epidermidis, vancomycin may be the most appropriate initial therapy for gram-positive organisms, although cefazolin remains effective in certain geographical areas.[36–38] Gram-negative therapy options include ceftazidime, cefepime, piperacillin–tazobactam, or a carbapenem.[35],[39] For patients who are intolerant of β-lactams, aztreonam may be considered as an alternative agent for gram-negative coverage.[35],[39] Fluoroquinolones represent an option for CAPD-associated peritonitis given the extent of distribution into the peritoneal cavity; however, oral therapy should not be used in severe cases of peritonitis. The increasing prevalence of fluoroquinolone-resistant gram-negative E. coli, however, is decreasing the utility of these agents.[40],[41]

Refractory peritonitis, presence of cloudy effluent after 5 days of IP therapy, may require removal of the catheter, suggesting an exit-site or tunnel infection. Oral antibiotic therapy, or intravenous therapy if severe, may be required for cases involving S. aureus or P. aeruginosa. When S. aureus is isolated, the infection usually necessitates the removal of the dialysis catheter. Vancomycin is recommended for MRSA (with or without rifampin) for 1 week, although monotherapy with vancomycin is adequate, particularly if the infected catheter is removed. Conversely, cefazolin alone is adequate for MSSA. Coagulase-negative Staphylococcus species do not require prompt catheter removal as they typically respond well to antimicrobial therapy. Methicillin resistance is common for S. epidermidis; thus, vancomycin is normally used. Enterococcus species or Streptococcus species should be treated with ampicillin if susceptible. Vancomycin should be used for ampicillin-resistant enterococcus; however, VRE require treatment with linezolid, quinupristin–dalfopristin, or daptomycin. In the case of culture-negative peritonitis and clinical improvement after 3 days of empiric coverage, a single agent directed toward gram-positive organisms may be continued for a total of 2 weeks.[35]

When a single gram-negative organism is cultured (e.g., E. coli, Klebsiella species, or Proteus species), therapy can be narrowed based on susceptibility. Isolation of P. aeruginosa most often indicates a severe infection, which may also involve the dialysis catheter. Therapy options include an antipseudomonal β-lactam such as ceftazidime, cefepime, or piperacillin–tazobactam with or without a fluoroquinolone or an aminoglycoside. In general, the β-lactam antimicrobials achieve peritoneal fluid concentrations exceeding typical minimum inhibitory concentrations for most commonly encountered facultative gram-negative and anaerobic bacteria.[35],[42],[43]

Aztreonam can be used in the case of severe immunoglobulin E (IgE)-mediated penicillin allergy. Polymicrobial peritonitis is uncommon and may indicate a more complicated intra-abdominal

---

process. Table 70-3 lists antimicrobial dosing guidelines for the treatment of peritonitis associated with CAPD.[44]

Table 70-3

Intraperitoneal Antibiotic Dosing Recommendations for CAPD Patients

	Intermittent Dosing[a]	Continuous Dosing[b] (mg/L)	
		LD	MD
Amikacin	2 mg/kg	25	12
Amoxicillin		250–500	50
Amphotericin			1.5
Ampicillin			125
Ampicillin–sulbactam	2 g every 12 hours	1,000	100
Aztreonam		1,000	250
Cefazolin	15 mg/kg	500	125
Cefepime	1,000 mg	500	125
Ceftazidime	1,000–1,500 mg	500	125
Ceftizoxime	1,000 mg	250	125
Ciprofloxacin		50	25
Daptomycin	40 mg every 4 hours	100	20
Fluconazole	200 mg every 24–28 hours		
Gentamicin	0.6 mg/kg	8	4
Imipenem–cilastatin	1 g twice daily	250	50
Levofloxacin	500 mg PO every 48 hours[c]		
Linezolid	200–300 mg PO daily		
Meropenem	500–1,000 mg daily		
Nafcillin			125
Oxacillin			125
Penicillin G		50,000 units	25,000 units
Polymixin B	150,000 units (IV) every 12 hours		
Quinupristin–dalfopristin	25 mg/L in alternate bags[d]		
Tobramycin	0.6 mg/kg	8	4
Vancomycin	15–30 mg/kg every 5–7 days	1,000	25

Empiric doses for patients with residual renal function (>100 mL/day urine output) should be increased by 25%.

[a] Per exchange, once daily.

[b] All exchanges.

[c] Oral levofloxacin is recommended to be given with weekly IP vancomycin in centers with low fluoroquinolone resistance.

[d] Given in conjunction with 500 mg IV twice daily.

CAPD, continuous ambulatory peritoneal dialysis; LD, loading dose; MD, maintenance dose; IV, intravenous.

Treatment of enterococcal peritonitis with intraperitoneal daptomycin in a vancomycin-allergic patient and a review of the literature. Perit Dial Int. 2013;33(4):353–357.

An example of an appropriate regimen for H.M. may include vancomycin plus cefepime or an aminoglycoside given intraperitoneally. The clinician should monitor culture and sensitivity results to adjust therapy based on guidelines, local sensitivity patterns, and therapeutic response.

FUNGAL CAPD-ASSOCIATED PERITONITIS

CASE 70-3, QUESTION 2: Two years later, H.M. presents with abdominal pain and cloudy dialysate fluid. Candida albicans is cultured from the dialysate fluid. No other organisms are present. How should H.M. be treated?

Fungal peritonitis is a rare complication of CAPD that is associated with significant morbidity and mortality. The rate of mortality in fungal peritonitis is approximately 25%.[35] Considering the high rate of failure of therapy, CAPD patients with fungal peritonitis should have their catheters removed.[37] Patients who have received prolonged or multiple courses of antibiotics, are on immunosuppressant therapy for a malignancy, transplant, or inflammatory disease, or have a postoperative or recurrent intra-abdominal infection are at increased risk for fungal peritonitis and should be treated with antibiotics.[3],[5],[45] Most cases are caused by Candida species, most commonly C. albicans; however, an increase in infection attributable to non-albicans species has emerged in many areas.[45] Empiric antifungal therapy should be broad and include most Candida species; echinocandins such as caspofungin, micafungin, or anidulafungin are the empiric drugs of choice. Amphotericin B may be administered intravenously (IV) or IP, but when given IP, conventional amphotericin B is very irritating to the peritoneum.[35] The azole antifungal agents can be administered orally, IV, or IP. Fluconazole is active against C. albicans, but it has dose-dependent activity against certain types of non-albicans species, such as Candida glabrata. In general,

---

fluconazole is the drug of choice for C. albicans; however, other options, such as a polyene or echinocandin, may be needed for azole-resistant Candida species. Therapy should continue for a minimum of 2 weeks after catheter removal, and the total duration may be based on severity and clinical response.[35]

H.M.'s treatment should include temporary catheter removal and administration of antifungal agents. Antifungal therapy with oral fluconazole 400 mg daily should be continued for at least 14 days.

SECONDARY PERITONITIS

Pathogenesis and Epidemiology

Secondary peritonitis usually occurs after fecal or urinary contamination of the peritoneal cavity or its surrounding structures.[2] The process leading to an infection commonly includes an acute perforation associated with appendicitis, diverticulitis, the uterus, neoplasm, and inflammatory bowel disease (IBD). Secondary peritonitis can also result from postoperative or posttraumatic perforation of the GI or genitourinary tract related to blunt trauma or ingestion of foreign material.[46],[47]

Localization of infection without eradication of bacteria results in intraperitoneal or visceral abscesses. Intraperitoneal abscesses occur most often in the right lower quadrant in association with appendicitis or a perforated peptic ulcer. Other causes can include diverticulitis, pancreatitis, IBD, trauma, and abdominal surgery. Visceral abscesses generally are found in the pancreas but may also occur in the liver, spleen, or kidney.[3]

Mortality with secondary peritonitis can be as high as 68%.[48] Timely source control with surgical intervention is imperative for clinical success of infections resulting from secondary peritonitis. Management with appropriate antimicrobial therapy, intensive care support, and the overall health of the patient are also critical for the outcome.[47]

Clinical Presentation and Diagnosis

CASE 70-4

QUESTION 1: R.C., a 48-year-old man, presents with severe abdominal pain and nausea. He states he has been taking nonsteroidal anti-inflammatory drugs (NSAIDs) for joint pain over the last 2 weeks. An esophagogastroduodenoscopy reveals a perforated peptic ulcer. Vital signs include temperature of 38.7°C and tachycardia (pulse, 105 beats/minute). Bowel sounds are absent. Laboratory values are WBC count, $16.5 \times 10^3/\mu L$ and BUN, 34 mg/dL. What signs and symptoms of secondary peritonitis does R.C. display?

Making the diagnosis of a localized intra-abdominal infection may be difficult, despite the presence of signs and symptoms typical of severe infection. Moderate-to-severe abdominal pain with anorexia, nausea, and vomiting are commonly experienced. Fevers with or without chills, tachycardia, sparse urination secondary to fluid loss into the peritoneum, faint or absent bowel sounds, and abdominal distention may accompany primary GI symptoms associated with peritonitis. Inflammation around the intestines and peritoneal cavity results in local paralysis and reflex rigidity of the abdominal wall muscles and the diaphragm, causing rapid and shallow respirations.[3] These signs usually are accompanied by an elevated WBC count with a predominance of neutrophils (left shift). The hematocrit (Hct) and BUN may be elevated as a result of dehydration. Initially, patients are usually alkalotic owing to emesis and hyperventilation, but in the later stages of peritonitis, acidosis usually occurs. Untreated or partially treated peritonitis can result in generalized sepsis and hypovolemic shock, in addition to, a gradual development of intraperitoneal abscesses. Therefore, patients with a sudden turn in disposition after treatment and recovery from peritonitis or abdominal surgery should be assessed for intraperitoneal abscess formation.[2],[3]

R.C. is likely to have a community-acquired intra-abdominal infection suggestive of a secondary peritonitis resulting from an acute perforated peptic ulcer after using an NSAID for 2 weeks. His current clinical status is highlighted by complaints of severe abdominal pain and nausea, fever with tachycardia, a significant elevation in WBC, and signs of dehydration with a BUN of 34 mg/dL.

CASE 70-4, QUESTION 2: Given these findings, what are the most likely pathogens for R.C.'s secondary peritonitis?

ETIOLOGY

The normal flora consistent with the perforated segment of the GI tract determines the most likely pathogens, consisting of both aerobes and anaerobes the more distal the source.[49] In general, the stomach and small bowel consist of few microbes, such as Candida species, lactobacilli, and oral streptococci, in the fasting state. However, the number and variety of gastric microbiota can increase with meals, achlorhydria (use of histamine [H2] blockers or proton pump inhibitors), obstruction, and presence of blood.[3] The most common facultative bacterium is E. coli, which is found in approximately 50% of cultures. A variety of other facultative gram-negative bacteria include Klebsiella species, P. aeruginosa, Proteus species, and Enterobacter species (Table 70-4).[2],[50–53] The presence of anaerobic bacteria in the culture is indicative of a polymicrobial infection with a predictable group of pathogens.[2],[33],[50–53] E. coli, enterococci, and a predominant presence of obligate anaerobes, including Bacteroides fragilis, P. melaninogenica, Peptococcus species, Peptostreptococcus species, and Fusobacterium species, are found in the ileum and colon of the large bowel. B. fragilis is the most frequently isolated obligate anaerobe after perforation of the colon.[3],[54] Anaerobic cocci (Peptostreptococcus) and facultative gram-positive cocci, such as streptococci, are also isolated.[3],[6],[51],[54] Enterococcus species are isolated less frequently.[3],[6],[51],[54] B. fragilis and E. coli are the most common pathogens found in blood culture samples after bacteremia related to an intra-abdominal infection.[3] Highly antibiotic-resistant strains of P. aeruginosa, Enterobacteriaceae producing ESBLs or carbapenemases, Acinetobacter species, and Enterococcus, as well as Candida species, are often isolated from hospitalized patients who experience secondary peritonitis.[3],[6]

Table 70-4

Bacteriology of Intra-Abdominal Infections[1,44–47,49]

Bacteria	Patients (%)

Facultative and aerobic gram-negatives	
Escherichia coli[a]	71
Klebsiella species	14
Pseudomonas aeruginosa	14
Proteus mirabilis	5
Enterobacter species	5
Anaerobes	
Bacteroides fragilis[a]	35
Other Bacteroides species	71
Clostridium species	29
Prevotella species	12
Peptostreptococcus species	17
Fusobacterium species	9
Eubacterium species	17
Aerobic gram-positives	
Streptococcus species	38
Enterococcus faecalis	12
Enterococcus faecium	3
Staphylococcus aureus	4

[a] Most common in community-acquired intra-abdominal infections.

Gram stain and culture do not need to be routinely obtained in community-acquired intra-abdominal infections before the initiation of antimicrobial therapy. It may be useful in health care–associated infections for detection of gram-positive cocci, yeast or multidrug-resistant pathogens.[3],[6] The presence of pleomorphic gram-negative bacilli, a strong odor, or tissue gas is strongly suggestive of infection with anaerobes, particularly B. fragilis.

R.C.'s secondary peritonitis is likely because of the presence of a facultative gram-negative bacteria, such as E. coli, Proteus, Klebsiella, or Enterobacter or possibly an obligate anaerobe, such as B. fragilis. R.C. does not present with a history of hospitalization or recent receipt of broad-spectrum antimicrobials; therefore, an infection caused by more resistant health care–associated pathogens (e.g., P. aeruginosa, ESBLs, carbapenemases) is less likely.

CASE 70-4, QUESTION 3: How should R.C. be treated? On the basis of clinical studies, what empiric antimicrobial therapy is appropriate for R.C. at this time?

Antimicrobial Therapy

EMPIRIC THERAPY

Therapy for secondary peritonitis should include early administration of antimicrobial agents directed at facultative gram-negative bacteria and obligate anaerobes, fluid therapy, and support of vital organ function, as well as source control measures. Antibiotics should be administered within 1 hour of presentation of septic shock and within 8 hours after hospital admission in those with stable hemodynamic or organ status.[6] Adequate source control involving surgical debridement and drainage, in conjunction with appropriate antimicrobial therapy, decreases morbidity and mortality.[2,3,55] In general, when an intra-abdominal infection is present, antimicrobial agents should be started immediately after appropriate specimens (e.g., blood, peritoneal fluid) have been obtained and before any surgical procedures are performed.[2,3,6,56] The parenteral route should be used to ensure adequate systemic and tissue concentrations, especially in patients in whom shock or poor perfusion of the muscles or GI tract precludes the use of oral administration. Table 70-2 outlines dosing recommendations for antibiotics commonly used in the treatment of intra-abdominal infections.

For mild-to-moderate community-acquired infections, empiric monotherapy with ertapenem, moxifloxacin, tigecycline, or cefoxitin is recommended. Moxifloxacin has good coverage against gram-positive and gram-negative aerobic organisms (excluding P. aeruginosa), in addition to anaerobic organisms, and penetrates well into inflamed GI tissue, peritoneal exudates, and abscesses.[53,57,58] Earlier concerns for resistance among Bacteroides species to moxifloxacin were reevaluated in recent studies and found moxifloxacin to be a safe and effective monotherapy option for mild-to-moderate community-acquired cIAI.[6,51,59,60] However, moxifloxacin should be used cautiously in infections with recent fluoroquinolone use. Tigecycline offers added in-vitro activity against resistant pathogens such as MRSA, VRE, and penicillin-resistant S. pneumoniae; however, tigecycline lacks activity against Proteus species and P. aeruginosa. Caution should be practiced when using tigecycline for severe infections, including cIAI, as the US Food and Drug Administration announced a boxed warning of increased risk for mortality and non-cure rates. Therefore, the use of tigecycline should be considered when alternative antibiotic options are not available. Ertapenem is another monotherapy option for mild-to-moderate community-acquired cIAI. In comparative trials of ertapenem versus piperacillin–tazobactam, the two agents were shown to be similar in efficacy and safety.[61–63] Because monotherapy has been shown to be efficacious in numerous trials, combination therapy is now rarely used. Combination therapy with either a cephalosporin or a fluoroquinolone (ciprofloxacin or levofloxacin) plus metronidazole is also reasonable.[6] For severe community-acquired intra-abdominal infections, meropenem, imipenem–cilastatin, doripenem, and piperacillin–tazobactam are empiric monotherapy options that may be used. An antipseudomonal third- or fourth-generation cephalosporin, fluoroquinolone (ciprofloxacin or levofloxacin), or aztreonam in combination with metronidazole represent alternative options for severe infections.[6,61]

Tertiary peritonitis is described as persistent peritonitis with systemic signs of sepsis even after appropriate management of the infection has been initiated.[3] As a health care–associated infection, tertiary peritonitis often presents in critically ill patients and those immunocompromised where adequate source control may be improbable. With tertiary peritonitis, pathogens can vary from those that are less virulent such as enterococci, including VRE, coagulase-negative Staphylococcal species, and Candida species to the more resistant health care–associated pathogens with little to no antibiotic options. Empiric use of meropenem, imipenem–cilastatin, doripenem, or piperacillin–tazobactam[6] should be reserved for health care–associated infections in cases of sepsis and presumed or documented multidrug-resistant pathogens. Two new combination antibiotics, ceftolozane/tazobactam and ceftazidime/avibactam, both used with metronidazole, were recently approved for cIAI (Table 70-2).[64],[65] Ceftolozane/tazobactam and ceftazidime/avibactam offer in-vitro activity against challenging resistant gram-negative pathogens, including ESBLs and AmpC-producing Enterobacteriaceae and multi-drug resistant P. aeruginosa. Ceftazidime/avibactam also has in-vitro activity against K. pneumoniae carbapenemases.[66],[67]

Empiric use of ampicillin–sulbactam is no longer recommended for complicated intra-abdominal infections because of increasing rates of E. coli resistance.[6],[68] Clindamycin and cefotetan are not recommended for community-acquired cIAI because of rising resistance rates from B. fragilis. The association of clindamycin with Clostridium difficile–associated diarrhea has also resulted in the use of other options.[6],[50],[61–63,69,70] With the risk of toxicity when using aminoglycosides, safer agents are now considered first-line treatment options. Fluoroquinolone-resistant E. coli has become more common in the community. Caution should be taken when using fluorquinolones empirically, particularly if hospital antibiograms indicate <90% susceptibility of E. coli.[6] Susceptibility patterns within the community and institutional antibiograms may assist with selection of optimal empiric antimicrobials when managing community-acquired cIAIs.

R.C. should receive antimicrobial therapy with activity against facultative gram-negative bacteria and anaerobes, including B. fragilis. Ertapenem 1 g IV every 24 hours would be an appropriate treatment for R.C.'s mild-to-moderate cIAI.

CASE 70-4, QUESTION 4: How long should R.C. receive antimicrobial therapy?

DURATION OF ANTIMICROBIAL THERAPY

Recommendations for the duration of therapy for intra-abdominal infection vary from 4 to 7 days and depend primarily on the patient's clinical response to therapy and need for surgical drainage.[6] In general, antimicrobial therapy should be continued until resolution of signs of infection takes place, including return of WBC count to normal and elimination of fever.

ENTEROCOCCAL INFECTION

CASE 70-5

QUESTION 1: B.B. is a 58-year-old, non-obese woman with gangrene of the bowel from strangulation. One day after undergoing surgical resection of the duodenum, she has a fever of 38.9°C, shaking chills, and abdominal pain. Laboratory values include a WBC count of $18.4 \times 10^3/\mu L$ and creatinine of 1.1 mg/dL. B.B.'s peritoneal fluid cultures grew E. coli, B. fragilis, C. albicans, and Enterococcus. Blood cultures are negative. Should she receive additional antimicrobial therapy active against Enterococcus?

Although Enterococcus is commonly cultured in patients with secondary peritonitis, its pathogenicity has been questioned. Enterococcus can cause serious infections (e.g., endocarditis, urinary tract infections), but it is less virulent in the setting of polymicrobial infections such as intra-abdominal infections.

An important issue is whether empiric treatment should include antibiotics with activity against Enterococcus. Some investigators believe that Enterococcus species are commensal organisms that need not be treated in most clinical settings. They point to clinical studies in which antibiotic regimens lacking in-vitro activity against Enterococcus have been successful. The pathogenicity of Enterococcus lies in its ability to enhance the formation of abscesses.[2],[3] The presence of enterococci suggests active disease; however, use of anti-enterococcal antibiotics has not shown to improve outcomes.[2],[71]

In general, coverage is warranted if Enterococcus is present in blood cultures or is the sole organism on culture.[3],[6] Anti-enteroccocal therapy is recommended in patients with nosocomial or health care–associated infections,[6] particularly those who received antibiotics selecting for Enterococcus spp. (e.g., cephalosporins), are immunocompromised, have postoperative infection, or have valvular heart disease or prosthetic intravascular materials.[6] If susceptible, Enterococcus species should be treated with ampicillin or piperacillin/tazobactam. Vancomycin should be reserved for ampicillin-resistant enterococcus, whereas VRE can be treated with linezolid or daptomycin. Because B.B.'s blood cultures are negative and ascitic culture has demonstrated mixed pathogens, Enterooccus coverage, specifically VRE, may not be necessary. B.B. should be treated with an antimicrobial regimen that has activity against gram-negative ...pathogens, anaerobes and susceptible enterococci for a postoperative infection.

CASE 70-5, QUESTION 2: Should B.B.'s antimicrobial therapy include an agent with antifungal activity?

ANTIFUNGAL THERAPY: TREATMENT OF CANDIDA

The need to treat Candida species as a solitary isolate or as part of a polymicrobial infection is controversial. Certainly, Candida has the potential to cause peritonitis, IP abscesses, and subsequent candidemia. Mortality resulting from Candida peritonitis ranges from 25% to 60%.[72] Risk factors for Candida peritonitis have included recurrent abdominal surgery, GI tract perforation, particularly in those untreated within the first 24 hours, surgical drains, intravenous and urinary catheters, severe sepsis, and colonization by Candida species.[72],[73] Significance for intra-abdominal candidiasis worthy of treatment rises when Candida species are isolated surgically or directly from an intra-abdominal collection (e.g., within 24 hours of drain placement) in patients with severe community-acquired or health care–associated infections.[6],[74] This may include patients who recently received immunosuppressive therapy for neoplasm, has a perforated gastric ulcer while on acid suppression, has malignancy, transplantation or inflammatory disease, or a postoperative or recurrent intra-abdominal infection.

Echinocandins and azoles are initial options for fungal peritonitis.[6],[20] Concerns about the toxicity of conventional amphotericin B have limited the use of this agent. To date, no clinical trials have assessed the efficacy and safety of lipid-based amphotericin B, azoles, or echinocandins in the treatment of intra-abdominal fungal infections. Fluconazole is considered an appropriate drug of choice for C. albicans.[6] For C. glabrata or other fluconazole-resistant species, an echinocandin (caspofungin, micafungin, or anidulafungin) or an amphotericin product is an appropriate option.[6] If critically ill, initial therapy with an echinocandin is recommended.

Therapy with an antifungal agent such as fluconazole 400mg daily is acceptable for B.B and the C. albicans isolated.

CASE 70-5, QUESTION 3: The surgical resident initiated piperacillin–tazobactam for the treatment of B.B.'s intra-abdominal infection. Should culture and sensitivity results be used to monitor for anaerobic activity?

ANAEROBIC BACTERIA

With the introduction of broad-spectrum antimicrobial agents with in-vitro activity against B. fragilis and a significant problem of increasing resistance, the choice of a specific antianaerobic agent has become more complex. Multiple mechanisms of resistance are encountered, and resistance rates differ among various geographic areas of the United States. Although Bacteroides resistance to metronidazole is rare,[20],[75] resistance to clindamycin has increased substantially.[20] Although the carbapenems and the β-lactamase inhibitor combinations are exquisitely active against Bacteroides, occasional resistance has been reported.

The Clinical and Laboratory Standards Institute has suggested that susceptibility testing be performed only to determine patterns of anaerobic susceptibility to new antimicrobial agents and to monitor susceptibility patterns periodically on a geographic and local basis.[76]

Because most anaerobes are cultured in the setting of mixed flora, isolation of individual components of a complex mixture can be time-consuming. In addition, most anaerobes are very slow growing, and it may take days to weeks for a definitive culture and sensitivity report. If specimens are not collected and transported in optimal media or in a timely manner, inaccurate or misleading results may be reported. The methods for susceptibility testing of anaerobic bacteria are not well standardized, and many hospital laboratories do not have resources to perform extensive culture and sensitivity testing. Routine cultures rarely impact the choice of antibiotic regimen, and thus the empiric choice of therapy usually determines the outcome.[77] Routine susceptibility testing for patient-specific cases is not recommended because of the prolonged time needed to achieve results, but it may be useful when resistant organisms are suspected or high-risk patients have been identified.[78]

Intra-Abdominal Abscess

CASE 70-6

QUESTION 1: R.K. is a 28-year-old woman with a history of diverticulitis, who presents with abdominal pain and distension, fever, and chills. An intra-abdominal abscess is visualized by CT scan. How did this abscess develop? What considerations should be taken into account in the selection of appropriate antimicrobial agents?

Abscesses are collections of necrotic tissue, bacteria, and WBCs that form during a period of days to years. They generally result from chronic inflammation and the body’s attempt to localize organisms and toxic substances by formation of an avascular fibrous wall. This process isolates bacteria and the liquid core from opsonins and antimicrobial agents.

Microbiology

Pathogens encountered in intra-abdominal abscesses often include facultative aerobic gram negatives (e.g., E. coli) and obligate anaerobes (e.g., B. fragilis).[46] Mixed infections involving E. coli or enterococci with B. fragilis have been associated with a synergistic mechanism responsible for late intraperitoneal abscess development.[79],[80]

ANTIMICROBIAL THERAPY

Abscesses pose a therapeutic challenge because they typically contain large bacterial inocula that are likely to include subpopulations of resistant bacteria.[55] Furthermore, the rate of penetration of antibiotics into abscesses is hindered by the low surface-to-volume ratio, low pH, and decreased permeability. Although percutaneous drainage or surgical debridement of R.K.’s abscess is crucial, adjunctive therapy with antimicrobial agents is warranted. The optimal antimicrobial agent should penetrate into the abscess in adequate concentrations and have an adequate spectrum of activity.[20],[55] R.K. should be placed on an antimicrobial regimen, such as piperacillin–tazobactam 3.375 g IV every 6 hours, that covers gram-negative bacteria and anaerobes.

INFECTIONS AFTER ABDOMINAL TRAUMA AND POSTOPERATIVE COMPLICATIONS

Risk factors for infection after penetrating abdominal trauma include the number, type, and location of injuries; the presence of hypotension; large transfusion requirements; prolonged operation; advanced age; and the mechanism of injury.[81]

Most investigators stress the importance of instituting antimicrobial therapy as close to the time of trauma as possible. Bozorgzadeh et al.[82] demonstrated a significant reduction in the incidence of postoperative infections when antibiotics were administered before surgical repair of the penetrating abdominal trauma.

Penetrating Trauma

CASE 70-7

QUESTION 1: T.I., a 19-year-old man, is admitted to the emergency department within 1 hour after sustaining a gunshot wound to the stomach and colon. He is to undergo emergency laparotomy. What antimicrobial therapy is appropriate at this time?

As with other types of intra-abdominal infections, antibiotics active against both aerobic and anaerobic pathogens should be used.

Anti-infective therapy has been studied in patients who have sustained penetrating trauma to the abdomen (usually from knife or gunshot wounds). In several comparative trials, single-drug therapy with cefoxitin was as effective as the combination of clindamycin or metronidazole plus an aminoglycoside.[83] In evaluating these studies, however, it is important to note that most patients did not sustain injuries to the colon, where the risk of infection is highest. Although the age of this patient suggests he would tolerate aminoglycoside therapy, monotherapy with cefoxitin or one of the β-lactamase inhibitor combinations would be appropriate.

Consensus guidelines regarding the duration of therapy were published by the Eastern Association for the Surgery of Trauma (EAST) Practice Management Group. These investigators reviewed all literature from 1976 to 1997 regarding the duration of antimicrobial use after penetrating abdominal trauma. They concluded that antimicrobial use should not exceed 24 hours in this patient population.[81]

CASE 70-7, QUESTION 2: How long should antibiotic therapy be administered to T.I.?

The shortest duration of antimicrobial therapy that has been shown to be effective has been 12 hours with the possibility that a short course (<48 hours) is as efficacious as 5-to 7-day course if antimicrobial therapy is promptly instituted.[6] Several other trials have confirmed no additional benefit exists in providing a longer treatment duration.[6],[77],[81],[84–86]

Because antimicrobial therapy carries a risk of adverse reactions, development of resistance, and unnecessary costs, short-term therapy seems warranted as long as it is instituted soon after the injury.[81],[87] If the initial dose of antibiotic is administered more than 3 to 4 hours after injury, therapy should be continued for 3 to 7 days because the incidence of infection in this circumstance is high.

Antimicrobial therapy was instituted soon after T.I. sustained the colonic injury; therefore, a short course of antimicrobial therapy is appropriate. Therapy should be continued for 24 hours.

Appendectomy

CASE 70-8

QUESTION 1: S.R. is a 12-year-old girl with a 2-day history of periumbilical pain migrating to the right lower quadrant, abdominal distension, fever of 39°C, diarrhea, and decreased bowel sounds. Her WBC count is 15.8 × $10^3/\mu L$. A presumptive diagnosis of acute appendicitis is made. What antimicrobial therapy is indicated, and for how long should it be continued?

Clinical manifestations commonly encountered with acute appendicitis include right lower quadrant abdominal pain, rebound tenderness, and low-grade fever complicated by nausea, vomiting, and anorexia.[3],[6],[35]

A variety of antimicrobial agents are effective in the treatment of acute appendicitis.[88–92] Antimicrobial therapy selection for uncomplicated appendicitis can follow those recommended for community-acquired intra-abdominal infection where therapy for less than 24 hours is sufficient.[6] Patients with gangrenous or perforated appendices are associated with the highest risk of infection. In several well-designed, randomized, placebo-controlled trials, therapy with imipenem–cilastatin, β-lactams, and β-lactamase inhibitor combinations has been found to be as effective as the combination of clindamycin or metronidazole plus an aminoglycoside.[27],[89],[91] Patients with gangrenous or perforated appendices who were afebrile for 48 hours have been treated for durations ranging from a single dose[92] to 3 to 5 days.[90]

S.R. should receive a preoperative dose of β-lactam antimicrobials with activity against facultative gram-negative and anaerobic bacteria, such as cefoxitin alone or cefazolin plus metronidazole (Table 70-2). Cost, potential side effects, and ease of administration guide selection of a specific agent. If a gangrenous or perforated appendix is found during surgery, antimicrobial therapy should be continued for a minimum of 3 to 5 days or until S.R. has been afebrile for 48 hours.

Urinary Tract Infections

Douglas N. Fish

CORE PRINCIPLES	CHAPTER CASES
1 Urinary tract infection (UTI) is usually bacterial in etiology, may be either acute or chronic, and may affect any part of the upper or lower urinary system. UTI is often classified as either uncomplicated or complicated based upon patient characteristics and on the clinical setting in which the infection is acquired (e.g., community-acquired vs. health care–acquired).	**Case 71-1 (Questions 1–6),** **Case 71-2 (Questions 1, 2)**
2 Uncomplicated UTI occurs in women who are otherwise healthy and have normal structure and function of the urinary tract. These infections are primarily caused by Escherichia coli (75%–95% of infections) and other gram-negative bacilli, as well as gram-positive organisms such as Staphylococcus saprophyticus and Enterococcus.	**Case 71-1 (Questions 1–3)**
3 Symptoms commonly associated with lower UTI (e.g., cystitis) include dysuria, frequent urination, suprapubic pain, hematuria, and back pain. Patients with upper tract infection (e.g., acute pyelonephritis) often present with similar findings as well as loin pain, costovertebral angle tenderness, fever, chills, nausea, and vomiting.	**Case 71-1 (Questions 1, 2),** **Case 71-5 (Questions 1–3)**
4 The cornerstone of effective treatment of UTI is appropriate selection and use of antibiotics. Resistance among E. coli and other uropathogens is increasing and is an important consideration in antibiotic selection. Consensus clinical guidelines recommend trimethoprim–sulfamethoxazole (TMP–SMX) for 3 days, nitrofurantoin for 5 days, or a single dose of fosfomycin as preferred first-line antibiotics for treatment of acute uncomplicated cystitis in women.	**Case 71-1 (Questions 1–6),** **Case 71-2 (Question 1),** **Tables 71-1, 71-2, 71-3**
5 Fluoroquinolones are commonly used for treatment of UTI and are highly effective. However, growing concerns of increasing resistance and potential adverse effects limit the use of fluoroquinolones in uncomplicated UTI to patients unable to receive other preferred agents because of drug resistance, allergies, or other contraindications. Similar recommendations restrict the use of β-lactam antibiotics for uncomplicated UTI.	**Case 71-1 (Question 3),** **Case 71-2 (Questions 1, 2),** **Case 71-3 (Question 1),** **Tables 71-1, 71-2, 71-3**
6 Complicated UTI is associated with abnormalities of the urinary tract that interfere with normal urine flow or function; men, children, patients with diabetes, pregnant women, and hospitalized patients are examples of commonly affected populations. Complicated infections are	**Case 71-1 (Questions 1–4),** **Case 71-2 (Question 1),** **Case 71-4 (Question 1),** **Case 71-10 (Questions 1, 2),**

	frequently caused by drug-resistant gram-negative bacilli or other pathogens with reduced antibiotic susceptibility. Antibiotic selection for complicated UTI should be guided by culture and susceptibility testing, and patients usually require longer durations of antibiotic therapy (7–14 days).	**Case 71-11 (Questions 1–3)**
7	Pyelonephritis may be more severe in presentation and is often associated with bacteremia and other complications. However, most cases are uncomplicated and can be treated on an outpatient basis with oral antibiotics such as fluoroquinolones. Patients who cannot take oral antibiotics or who are clinically unstable should be hospitalized for initial treatment with intravenous antibiotics.	**Case 71-5 (Questions 1–5), Tables 71-1, 71-2, 71-5**

8	Recurrent UTI may be caused by either reinfection or relapse because of treatment failure. Relapse usually occurs within two weeks of the original infection and is caused by the same pathogen. Selection of antibiotics for treatment of relapsed UTI should be guided by culture and susceptibility testing, and the duration of antibiotic therapy should be at least 2 weeks in length.	**Case 71-6 (Questions 1–3, 6-8), Case 71-7 (Questions 1, 2)**
9	Recurrent UTI, which occurs more than 2 weeks after the original infection, is treated as a new infection with antibiotic considerations similar to those for the initial infection. Women with frequent infections (3 or more/year) may be considered for chronic prophylaxis therapy. Women with identifiable causes of reinfection (e.g., associated with sexual intercourse) may self-administer prophylactic antibiotics.	**Case 71-6 (Questions 4, 5, 7, 8),** **Tables 71-3, 71-4**
10	Asymptomatic bacteriuria ($\geq 10^5$ bacteria per milliliter of urine in the absence of clinical signs/symptoms of UTI) is particularly common in children, the elderly, pregnant women, and in patients with diabetes. Treatment of asymptomatic bacteriuria for prevention of subsequent infection and associated complications is routinely recommended in children and pregnant women. However, treatment of the elderly and patients with diabetes has not shown clear benefits and is not currently recommended.	**Case 71-7 (Questions 3, 4),** **Case 71-8 (Questions 1, 2),** **Case 71-9 (Questions 1, 2)**
11	Prostatitis is a relatively common infection in men and is caused by bacteria similar to those causing uncomplicated UTI in women. Acute bacterial prostatitis is usually treated with either a fluoroquinolone or TMP–SMX for a period of 2 to 4 weeks. Chronic prostatitis persists in a small percentage of men after acute infection and is usually treated for 4 to 6 weeks, although longer courses may sometimes be required.	**Case 71-12 (Questions 1, 2)**

URINARY TRACT INFECTION

Incidence, Prevalence, and Epidemiology

Urinary tract infection (UTI) is an acute or chronic infection, usually bacterial in origin, that may affect any part of the upper or lower urinary system.

Infections of the bladder are referred to as cystitis, and infections involving the parenchyma of the kidneys are known as pyelonephritis. UTIs occur frequently in both community and hospital environments and are the most common bacterial infections in humans.[1–3] The term UTI encompasses a spectrum of clinical entities ranging in severity from asymptomatic infection to acute pyelonephritis with sepsis.[1–4] Approximately 8 to 9 million cases of acute cystitis and 250,000 cases of acute pyelonephritis occur annually in the United States, resulting in more than 100,000 hospitalizations.[2,5,6] Direct costs associated with the diagnosis and treatment of UTI have been estimated at approximately $3 billion annually in the United States.[3,6,7] UTI is predominantly a disease of females with more than 50% of all women experiencing at least one infection during their lifetime.[2,5] The overall likelihood of developing a UTI is approximately 30 times higher in women than in men.[3,7,8] Women have more UTIs than men, probably because of anatomic and physiologic differences. The female urethra is relatively short and allows bacteria easy access to the bladder. In contrast, males are partly protected because the urethra is longer and antimicrobial substances are secreted by the prostate.[1,3,7,8]

Approximately 1% of boys and 3% to 5% of girls experience at least one UTI during childhood and 30% to 50% of these will have at least one recurrence.[9] The incidence of UTI in neonates is about 1% and is more frequent in male neonates, frequently because of congenital structural abnormalities.[10] The mortality rate among newborns with UTI was earlier reported to be as high as 10%[10]; however, this rate is now much lower because of an increased awareness of the high frequency of UTI in children, improved diagnostic techniques, and more effective management.[10] UTIs in males also occur with increased frequency after age 50, when prostatic obstruction, urethral instrumentation, and surgery influence the infection rate. Infection in younger men is rare and requires careful evaluation for urinary tract pathology.[11,12]

Of women between the ages of 15 and 24 years, 1% to 5% have bacteriuria; the incidence increases 1% to 2% for each decade of life, and approximately 10% to 20% of women are bacteriuric after age 70.[1,8,13,14] In general, 5% to 20% of all elderly living at home have bacteriuria, and this number increases to 20% to 50% in extended care facilities and 30% in hospitals.[3,13,15,16] For those 65 years or older the frequency of UTI continues to rise with increasing age. Most UTI in these patients are asymptomatic, but it may also result in symptomatic infection.[13,15,16] Reasons for higher UTI rates in elderly persons include the high prevalence of prostatic hypertrophy in men, incomplete bladder emptying caused by underlying diseases or medications, dementia, and urinary and fecal incontinence.[8,15–17] Whether bacteriuria in old age is associated with decreased survival is controversial[17,18]; however, the presence of asymptomatic bacteriuria is associated with decreased functional ability of institutionalized persons,[13,15] and symptomatic UTI has been independently associated with a threefold increased risk of vertebral fractures.[19]

Etiology

UNCOMPLICATED VERSUS COMPLICATED INFECTIONS

An important distinction in the characterization and treatment of UTI is that of uncomplicated versus complicated infections. Uncomplicated UTI, either cystitis or pyelonephritis, occurs in women who have normal structure and function

---

of the genitourinary tract and who have no other factors which would put them at risk for more severe or complex infections.[3],[5],[20] By contrast, complicated infections are those which are associated with conditions that increase the risk for acquiring infection, the potential for serious outcomes, or the risk for therapy failure. Such conditions are often associated with genitourinary tract abnormalities that may interfere with normal urine flow. Infections in men, children, and pregnant women are automatically considered complicated, as are those which are health care–associated in origin. Other examples of complicated infections include those associated with structural and neurologic abnormalities of the urinary tract, metabolic or hormonal abnormalities, impaired host responses, instrumentation and catheterization of the urinary tract, and those caused by unusual pathogens (e.g., yeasts, Mycoplasma).[3],[5],[20] Uncomplicated infections are invariably community-acquired and are caused by the organisms typical to that etiology. Complicated UTI may be caused by pathogens associated with either community-acquired or health care–associated infections, depending on the source of bacterial acquisition and specific underlying patient risk factors. Complicated infections are also more often polymicrobial in etiology, associated with more antibiotic-resistant pathogens, and generally require a longer duration of therapy.

COMMUNITY-ACQUIRED INFECTIONS

Most UTIs are caused by gram-negative aerobic bacilli from the intestinal tract. Escherichia coli cause 75% to 95% of community-acquired, uncomplicated UTIs.[1],[3],[20] Coagulase-negative staphylococci (e.g., Staphylococcus saprophyticus) account for another 5% to 20% of UTIs in younger women.[1],[3],[5] Other Enterobacteriaceae (e.g. Proteus mirabilis, Klebsiella) and Enterococcus faecalis also are common pathogens.[1],[3],[20] Uncomplicated infections are nearly always caused by a single pathogen.

HEALTH CARE–ASSOCIATED INFECTIONS

UTIs occur in up to 10% of hospitalized patients and represent 20% to 30% of all nosocomial infections.[21–23] E. coli remains the most common pathogen in hospital-acquired or other complicated UTI, but it is responsible for only 20% to 30% of these infections. Other gram-negative organisms, such as Pseudomonas aeruginosa, Klebsiella, Proteus, Enterobacter, and Acinetobacter, cause significantly more infections (up to 25%) than in the community setting.[5],[22],[23] Enterococcus is also a common pathogen in hospital-acquired UTIs and causes approximately 15% of infections.[22],[23] UTIs because of Staphylococcus aureus are usually the result of hematogenous spread, although this pathogen is also associated with urinary catheterization.[1],[22–24] Finally, Candida is a common pathogen in hospital-acquired infections and may be involved in 20% to 30% of cases.[21–23] In contrast to the usually monomicrobial uncomplicated infections, UTIs associated with structural abnormalities or indwelling urinary catheters are often caused by multiple pathogens.[1],[21–24]

Pathogenesis and Predisposing Factors

The typical pathway for the spread of bacteria to the urinary tract is the ascending route. A UTI usually begins with heavy and persistent colonization of the introitus (i.e., vaginal vestibule and urethral mucosa) with intestinal bacteria. Colonization of the urethra leads to retrograde infection of the bladder and the development of cystitis.[25],[26]

The bladder has defense mechanisms that prevent spread of the infection after urethral colonization has occured.[1],[3],[22] Urination washes bacteria out of the bladder and is effective if urine flows freely and the bladder is emptied completely. Substances in the urine, including organic acids (which contribute to low pH) and urea (which contributes to high osmolality), are antibacterial. The bladder mucosa also has antibacterial properties.[1],[3],[22] Lastly, other substances, including immunoglobulin A and glycoproteins (e.g., Tamm–Horsfall protein), are actively secreted into the urine and prevent adherence of bacteria to uroendothelial cells.[22],[25],[26]

Focal renal involvement leading to pyelonephritis may result from the spread of bacteria via the ureters and may be facilitated by vesicoureteral reflux or decreased ureteral peristalsis. Ureteral peristalsis is decreased in pregnancy, by ureteral obstruction, or by gram-negative bacterial endotoxins.[1],[25],[26] Reflux can be produced by cystitis alone or by anatomic defects.

A variety of factors contribute to the development of UTI, for example expression of bacterial virulence factors such as specific adhesin molecules, bacterial polysaccharides, and bacterial enzymes. Other factors predisposing to the development of UTI are dependent on the host and may include extremes of age, female sex, sexual activity, use of contraception, pregnancy, urinary tract instrumentation or catheterization, urinary tract obstruction, neurologic dysfunction, renal disease, previous antimicrobial use, and expression of A, B, and H blood group oligosaccharides on the surface of epithelial cells.[1–3,17,25,27]

The incidence of bacteriuria in pregnant women is as high as 17%, which is approximately twice that of similarly aged nonpregnant women.[1,13,28,29] The incidence of acute symptomatic pyelonephritis in pregnant women with untreated bacteriuria also is high and may reach 40%.[3] Many factors contribute to the increased susceptibility of the pregnant female to infection; these include hormonal changes, anatomic changes, progressive urinary stasis, and glucose in the urine.[28,29] Hormonal changes have also been linked to a significantly higher risk of UTI in menopausal women.[3] Estrogen promotes an acidic vaginal pH and proliferation of normal flora such as Lactobacillus, both factors which reduce pathogenic colonization of the vagina. Reduction of estrogen production during menopause allows significant colonization of the vaginal tract with E. coli and other enteric bacilli, thus predisposing to subsequent infection.[3]

Renal disease increases the susceptibility of the kidney to infection.[1] The incidence of UTI among renal transplant recipients ranges from 35% to 80% without prophylactic antibiotic therapy.[30] Patients with spinal cord injuries, stroke, atherosclerosis, or diabetes may have neurologic dysfunction predisposing to UTI. The neurologic dysfunction can cause urinary retention, requiring catheterization. Furthermore, prolonged immobilization facilitates hypercalciuria and stone formation in some of these patients.[1,5,25]

Previous antimicrobial use (within the previous 15–28 days) for UTI or other infections increases the relative risk for UTI in women threefold to sixfold.[3] The proposed mechanism for this is alteration of normal flora of the urogenital tract and predisposition to colonization with pathogenic bacterial strains.[2,3]

Diabetes mellitus is associated with a higher risk for UTI because of glucose in the urine, promoting bacterial growth and impairing leukocyte function. Anatomic, neurologic, and immunologic abnormalities of the urinary tract in diabetics contribute to the risk of infection, often because of more frequent urinary tract instrumentation.[31,32] Several studies have documented a twofold to threefold increase in UTI in women with diabetes compared to those without; rates of relapses and reinfections, as well as complications such as pyelonephritis, are also higher.[31–33] Autonomic neuropathy associated with diabetes also contributes to increased frequency and severity of UTI.[25,31,32]

Finally, studies have supported an association between sexual intercourse and UTI among otherwise healthy women.[2,3,25,34] Specific contraceptive practices, particularly the use of spermicides, and the use of a diaphragm, cervical cap, or condom in combination with spermicidal jelly increases the risk of UTI compared with the use of the barrier method alone.[2],[27],[34] Diaphragm users are approximately 3 times more likely to experience a UTI than women using other contraceptive methods, especially when the diaphragm is used in conjunction with spermicidal jelly.[2],[27] Oral contraceptive use has also been linked with increased risk of UTI, although this is still unclear.[2],[3],[27],[34] The exact mechanisms of infection related to sexual intercourse and contraceptive methods are unclear but appear to be related to alterations in vaginal flora that allow for bacterial overgrowth and subsequent infection.[1–3]

URINARY CATHETERS

Instrumentation or catheterization of the urinary tract is an important predisposing factor for health care–associated UTI. Catheter-associated UTI, the most common type of hospital-acquired infection, occurs in up to 30% of catheterized patients.[23] Catheterization and other forms of urologic instrumentation are present as risk factors for infection in 65% to 95% of all hospital-acquired UTI.[22] These UTIs also are a major cause of nosocomial gram-negative bacteremia.[21],[23] Other urologic procedures, such as cystoscopy, transurethral surgery, prostate biopsy, and upper urinary tract endoscopy, are much less likely to result in infection unless there is preexisting bacteriuria or other contaminated sites (e.g., prostate, renal stones). Any obstruction to the free flow of urine (e.g., urethral stenosis, stones, tumor) or mechanical difficulty in evacuating the bladder (e.g., prostatic hypertrophy, urethral stricture) also predisposes patients to UTI. Furthermore, infections associated with urethral or renal pelvic obstruction can lead to rapid destruction of the kidney and sepsis.[1]

Catheter infection can occur by bacterial entry from several routes. The urethral meatus and the distal third of the urethra normally are colonized by bacteria; therefore, initial catheter insertion can introduce bacteria into the bladder. Bacteria contaminating catheter junctions and the urine collection bag can migrate through the catheter lumen to the bladder, initiating infection.[23] The extraluminal space in the urethra also has been considered a potential route of contamination. The risk of infection is directly related to catheter insertion technique, care of the catheter, duration of catheterization, and the susceptibility of the patient. A diagnostic or single, short-term catheterization is associated with a much lower risk of infection than indwelling, long-term catheterization.[23] Despite careful technique, the risk of contaminating a sterile bladder with urethral bacteria is always present. The incidence of infection after a single catheterization is 1% in healthy young women and 20% in debilitated patients. Each reinsertion of the catheter introduces a risk of infection.[23]

Infections have been reduced dramatically by the closed sterile drainage system, the most common type of catheter currently in use. With this system, the drainage tube leads from the catheter directly to a closed plastic collection bag. The overall incidence of infection from the closed system with careful insertion and maintenance is about 20%; the risk increases to 50% after 14 days of catheterization.[23] Condom catheters are associated with a lower incidence of bacteriuria than indwelling urethral catheters. These catheters avoid problems associated with insertion of a tube directly into the urinary tract; nevertheless, urine within the catheters may have high concentrations of organisms so that colonization of the urethra and subsequent cystitis may develop.[23]

Application of antibacterial substances to the collection bag or the catheter–urethral interface does not decrease the incidence of bacteriuria.[23],[35],[36] The use of antimicrobial-coated catheters (e.g., silver, rifampin plus minocycline) has been shown in some studies to decrease rates of bacteriuria and UTI.[23],[35],[36] The overall effects of these catheters on infection rates, patient outcomes, and antibiotic resistance are not known, however. The routine use of antibiotic-coated catheters is not currently recommended.[23],[35]

Clinical Presentation

Symptoms commonly associated with lower UTI (e.g., cystitis) include burning on urination (dysuria), frequent urination, suprapubic pain, blood in the urine (hematuria), and back pain. Patients with upper tract infection (e.g., acute pyelonephritis) may also present with loin pain, costovertebral angle (CVA) tenderness, fever, chills, nausea, and vomiting.[1–5,37]

Clinical signs and symptoms correlate poorly with either the presence or the extent of the infection. Symptoms common to lower UTI often are the only positive findings in upper UTI (i.e., subclinical pyelonephritis).[1],[4] The probability of true infection in women who present with one or more symptoms of UTI is only about 50%.[38] The presence of dysuria, back pain, pyuria, hematuria, bacteriuria, and a history of previous UTI may enhance the probability of true infection; the absence of dysuria or back pain, and history of vaginal discharge or irritation significantly decrease the likelihood of infection.[38],[39] The combination of dysuria plus urgency or frequency in the absence of vaginal discharge or irritation increases the probability of true infection to greater than 90%.[38],[39] Fever, chills, flank pain, nausea and vomiting, or CVA tenderness are highly suggestive of acute pyelonephritis rather than cystitis. [4],[5],[37] Many elderly patients with UTI are asymptomatic without pyuria. Additionally, because many patients have frequency and dysuria, it is difficult to distinguish between noninfectious and infectious causes based on symptoms.[1] Nonspecific symptoms, such as failure to thrive and fever, may be the only manifestations of UTI in neonates and children younger than 2 years of age.[1]

Diagnosis

Diagnosis of UTI based on clinical findings alone is accurate in only approximately 70% of patients.[40] Urinalysis (UA) is a series of laboratory tests commonly performed in patients suspected of having a UTI; in combination with appropriate clinical findings, the UA effectively improves the overall diagnostic accuracy for UTI.[41] A technician first performs a macroscopic analysis by describing the color of the urine; measuring its specific gravity; and estimating the pH and glucose, protein, ketone, blood, and bilirubin contents using a rapid “dipstick” method. Then the urine sediment, obtained by centrifugation, is examined under a microscope for the presence and quantity of leukocytes, erythrocytes, epithelial cells, crystals, casts, and bacteria.

Rapid diagnostic dipstick tests are widely available and easily performed. The nitrite test detects nitrite formation from the reduction of nitrates by bacteria. Although a positive nitrite reading is useful, false-negative results do occur.[40] Dipstick testing can also be used to perform the leukocyte esterase test, which detects the esterase activity of activated leukocytes in the urine. A positive test correlates well with significant pyuria[42]; however, both false-negative and false-positive findings can occur with the leukocyte esterase panel as well.[40] Nitrite and leukocyte esterase tests are useful in ruling out the presence of infection if results of both tests are negative, whereas positive results of both tests in combination are highly suggestive of the presence of infection.[40]

Microscopic examination of urine sediment in patients with documented UTI reveals many bacteria (usually >20 per high-power field [HPF]). Gram staining of uncentrifuged (“unspun”) urine shows at least one organism per immersion oil field and usually correlates with a positive urine culture. Pyuria

---

(i.e., ≥8 white blood cells [WBC] per milliliter [mL] of unspun urine or 2–5 WBC/HPF of centrifuged urine) is frequently seen in patients with UTI. WBC casts in the urine strongly suggest acute pyelonephritis.[1],[41]

The gold-standard criterion for the diagnosis of UTI is the urine culture with a positive UA.[1–3,37] Proper interpretation of these cultures depends, however, on appropriate urine collection techniques. Urinating into a sterile collection cup using the midstream clean-catch technique is the most practical method of urine collection. This method of urine specimen collection is especially useful for male patients, but it is less useful in female patients because contamination is extremely difficult to avoid.[1] The external urethral area must first be thoroughly cleaned and rinsed, then the urine specimen collected after initiation of the urine stream (hence “midstream”).

Urinary catheterization for a urine culture sample yields fairly reliable results if performed carefully. However, infections can result from the procedure itself because organisms might be introduced into the bladder at the time of catheterization.

Suprapubic bladder aspiration generally is not painful and is quite reliable. It is not practical for routine office or clinic practice, but it may be useful when voided urine samples repeatedly yield questionable results or when patients have voiding problems. Because contamination is negligible, any number of bacteria found by this method reflects infection.[1–3]

Urine must be plated on culture media within 20 minutes of collection to avoid erroneously high colony counts from bacterial growth in urine at room temperature. Otherwise, urine should be promptly refrigerated until it can be cultured. Colony counts are also affected by the concentration of bladder urine; bacterial counts are higher in first-voided morning urines compared with those obtained from the same patient later in the day.[1],[37]

Greater than 10^5 colonies of bacteria/mL cultured from a midstream urine specimen confirms a UTI. A single, carefully collected urine specimen provides 80% reliability, and two consecutive cultures of the same organism are virtually diagnostic.[1–3] It is important to understand that the classic definition of UTI as greater than or equal to 10^5 bacteria/mL is fairly inaccurate in diagnosing patients with UTI. Approximately 30% to 50% of actual cases of acute cystitis have less than 10^5 bacteria/mL.[5],[13] In a symptomatic patient, using a definition of greater than or equal to 10^2 bacteria/mL is more accurate and avoids failure to diagnose infection in many patients.[5]

Diagnosis of UTI in men also requires different interpretation of laboratory data. Contamination of urinary specimens is much less likely to occur in men compared with women, and numbers of bacterial colonies in specimens are therefore much lower. Greater than 10^3 bacteria/mL is thus highly suggestive of UTI in men.[11],[12] In addition, although a positive nitrite test in a symptomatic man is highly indicative of the presence of an acute UTI, a negative nitrite test does not necessarily exclude infection and should be confirmed with a urine culture.[43]

Diagnosis of UTI in children is particularly problematic because of the difficulties and high contamination rates associated with commonly used methods of urine specimen collection. Suprapubic aspiration is the most accurate method in children, followed by urinary bladder catheterization.[3],[37] Although clean-catch and bag methods (i.e., collecting urine into a bag placed around the urogenital area) are most susceptible to contamination and inaccurate results, they are also the most preferred methods for parents and health care personnel because they are simple and noninvasive. The choice of diagnostic tests for children will therefore vary and be based on the experience, skill, and preferences of those involved with the child.[37]

Simplified culture methods such as the filter-paper method (e.g., Testuria-R), dip-slide method (e.g., Uricult), and pad-culture method (Microstix) are as reliable as traditional laboratory methods for bacterial identification and quantification. The filter-paper method is relatively inexpensive but does not differentiate between gram-positive and gram-negative organisms. The dip-slide and pad-culture methods are accurate, differentiate between gram-positive and gram-negative organisms, and are similar in cost. The dip-slide method has the added advantages of ease of storage and a nitrite indicator pad.

Overview of Drug Therapy

The cornerstone of effective treatment of UTI is the appropriate selection and use of antibiotics. Antibiotic treatment of UTI has been well studied and, compared to many other infectious diseases, the choice of specific antibiotic and duration of therapy for acute, uncomplicated infections are reasonably clear. Recently published consensus guidelines from the Infectious Diseases Society of America (IDSA) and the European Society for Microbiology and Infectious Diseases (ESMID) recommend a 5-day course of nitrofurantoin, trimethoprim–sulfamethoxazole (TMP–SMX) for 3 days, or a single dose of fosfomycin trometamol as first-line antibiotics for treatment of acute uncomplicated cystitis in women.[20] Whereas nitrofurantoin and TMP–SMX are familiar agents, fosfomycin is a previously little used antibiotic which has been available for many years. However, it has recently made a resurgence in clinical use because of low rates of resistance among common uropathogens. Fosfomycin also has usefulness against multidrug-resistant pathogens which are becoming more common in certain practice settings; these include methicillin-resistant S. aureus, vancomycin-resistant enterococci, and extended spectrum β-lactamase (ESBL)-producing gram-negative bacteria.[20],[44] Fluoroquinolones and β-lactam antibiotics, such as amoxicillin–clavulanate or various cephalosporins, are recommended by the IDSA/ESMID guidelines as alternative agents for treating acute uncomplicated cystitis.[20] These same guidelines recommend fluoroquinolones, cephalosporins, aminoglycosides, TMP–SMX, extended-spectrum penicillins (i.e., piperacillin–tazobactam), or a carbapenem for the treatment of acute pyelonephritis in women.[20] The choice of a specific agent for pyelonephritis depends primarily on whether or not the patient is hospitalized or treated as an outpatient, local susceptibility patterns, and whether therapy is empiric or based on known susceptibilities. The duration of therapy for acute pyelonephritis ranges from 5 to 14 days and is dependent on which specific antibiotic is being used.[20] Parameters for monitoring response to treatment of either uncomplicated cystitis or pyelonephritis are primarily resolution of clinical signs and symptoms, and repeat urinary cultures are not usually required. Patients with complicated UTI or recurrent infections may require additional monitoring and long-term follow-up, and antibiotic selection must be guided by culture and susceptibility (C&S) testing. Patient monitoring related to the safety and tolerability of antibiotic therapy is required regardless of type of infection, as is effective patient counseling.

LOWER URINARY TRACT INFECTION

Initial Patient Evaluation and Determining Goals of Therapy

CASE 71-1

QUESTION 1: V.Q., a 20-year-old woman with no previous history of UTI, complains of burning on urination, frequent urination of a small amount, and bladder pain. She has no fever or CVA tenderness. A clean-catch midstream urine sample shows gram-negative rods on Gram stain. A urine sample for culture and susceptibility testing is ordered, and the results of a UA are as follows:

Appearance, straw-colored (normal, straw)
Specific gravity, 1.015 (normal, 1.002–1.028)
pH, 8.0 (normal, 5.5–7.0)
Protein, glucose, ketones, bilirubin, and blood, all negative (normal, all negative)
WBC, 10 to 15 cells/LPF (normal, 0–2 cells/LPF)
Red blood cells (RBC), 0 to 1 cells/LPF (normal, 0–2 cells/LPF)
Bacteria, many (normal, 0 to rare)
Epithelial cells, 3 to 5 cells/LPF (normal, 0 to few cells/LPF)

Based on these findings, V.Q. is presumed to have a lower UTI. What should be the goals of therapy of V.Q.'s infection at this time? What factors should be considered before selecting an antibiotic for V.Q.?

The goals of therapy for treatment of acute cystitis are to effectively eradicate the infection and prevent associated complications, while minimizing adverse effects and costs associated with drug therapy. To accomplish these goals, selection of a specific antimicrobial agent should be made after considering several factors: (a) most likely pathogens, (b) resistance rates within the specific geographic area, (c) desired duration of therapy, (d) clinical efficacy and toxicity profiles of various agents, (e) cost and availability of specific agents, and (f) patient characteristics such as allergies, compliance history, and underlying comorbidities.[20] Because resistance rates among various pathogens vary considerably among geographic areas, clinicians must be familiar with resistance rates prevalent within their specific practice area.[20,45,46]

Drug treatment of a lower UTI often is started before C&S results are known because the most probable infecting organisms and their susceptibility to antibiotics can be predicted reasonably well (Table 71-1). Approximately 75% to 95% of community-acquired infections are caused by Enterobacteriaceae (especially E. coli). Although these organisms may be sensitive to ampicillin, amoxicillin, and the sulfonamides (such as TMP–SMX), resistance to these agents is common.[45–49] Ampicillin resistance occurs in 25% to 70% of community-acquired isolates[45–49]; resistance nationwide is currently about 30% to 40%.[1,5,20,45–49] TMP–SMX has been a traditional agent of choice for many years; however, TMP–SMX resistance has significantly increased in recent years and may be as high as 20% to 40% among community-acquired E. coli isolates in some geographic areas.[20],[45–49] Although traditionally associated with hospital-acquired infections, resistance among E. coli and Klebsiella caused by production of ESBL enzymes which confer resistance to penicillins and cephalosporins has also been steadily increasing among community-acquired pathogens.[50],[51] Another relatively common organism is S. saprophyticus. Most strains are susceptible to sulfonamides, TMP–SMX, penicillins, and cephalosporins. Commonly used medications and doses are shown in Table 71-2.

ROLE OF URINE CULTURES

CASE 71-1, QUESTION 2: Is it necessary to order a pretreatment urine C&S test for V.Q.?

Many investigators question the value of pretreatment urine cultures for acute uncomplicated UTI.[1],[2],[5],[20] Women with lower UTI usually have pyuria on UA and respond rapidly to appropriate antimicrobial treatment. Pyuria may be a better predictor of treatable infection than the colony count obtained on urine culture. Furthermore, the urine culture accounts for a large portion of the cost of treating a patient with a UTI.[52] Consequently, in patients such as V.Q. with uncomplicated, acute, lower UTI, it is more cost-effective to order a UA and, if pyuria is present on UA, to forego a urine culture. Instead, the patient should be empirically treated with a conventional course of antibiotic therapy. If V.Q. remains symptomatic 48 hours later, a C&S test can then be ordered. Considerations are quite different in patients with complicated infections. In complicated UTI, predisposing factors that lead to infection and frequent history of previous antibiotic use make both causative pathogens and associated antibiotic susceptibilities much less predictable. Use of C&S testing is therefore commonly recommended for treatment of complicated UTI in order to choose appropriate antibiotics.[1–3,5,20]

Table 71-1

Overview of Treatment of Urinary Tract Infections

Organisms Commonly Found	Antibacterial of Choice
Uncomplicated UTI	
Escherichia coli	TMP–SMX[a]
Proteus mirabilis	TMP–SMX[a]
Klebsiella pneumoniae	TMP–SMX[a]
Enterococcus faecalis	Ampicillin, amoxicillin
Staphylococcus saprophyticus	First-generation cephalosporin or TMP–SMX
Complicated UTI[b,c]	

E. coli	First-, second-, or third-generation cephalosporin; TMP–SMX[c]
P. mirabilis	First-, second-, or third-generation cephalosporin
K. pneumoniae	First-generation cephalosporin; fluoroquinolone
Enterococcus faecalis	Ampicillin or vancomycin ± aminoglycoside
Pseudomonas aeruginosa	Antipseudomonal penicillin ± aminoglycoside; ceftazidime; cefepime; fluoroquinolone; carbapenem
Enterobacter	Fluoroquinolone; TMP-SMX; carbapenem
Indole-positive Proteus	Third-generation cephalosporin; fluoroquinolone
Serratia	Third-generation cephalosporin; fluoroquinolone
Acinetobacter	Carbapenem; TMP-SMX
Staphylococcus aureus	Penicillinase-resistant penicillin; vancomycin

[a] Caution in communities with increased resistance (>10%–20%).

[b] Drug selection based on culture and susceptibility testing when possible.

[c] Oral therapy when appropriate. Nitrofurantoin, fosfomycin, fluoroquinolone, or cephalosporins should be used in areas with increased TMP–SMX resistance.

TMP–SMX, trimethoprim–sulfamethoxazole; UTI, urinary tract infection.

INITIAL ANTIBIOTIC SELECTION

CASE 71-1, QUESTION 3: What antibiotics may be appropriate for treatment of V.Q.'s infection?

Table 71-2

Commonly Used Oral Antimicrobial Agents for Acute Urinary Tract Infections[1–3,5,29,47,48,91]

	Usual Dose				
Drug	**Adult**	**Pediatric**	**Pregnancy[a]**	**Breast Milk[a]**	**Comments[b]**
Amoxicillin	250 mg every 8 hours or 3 g single dose	20–40 mg/kg/day in 3 doses	Crosses placenta (cord) = 30% (maternal)[c]	Small amount present	High resistance rates, not for empiric use.
Amoxicillin + potassium clavulanate	500 + 125 mg every 12 hours	20 mg/kg/day (amoxicillin content) in 3 doses	Unknown	Unknown	
Ampicillin	250–500 mg every 6 hours	50–100 mg/kg/day in 4 doses	Crosses placenta	Variable amount; milk = 1–30% of serum[c]	High resistance rates, not for empiric use. Should be taken on an empty

					stomach.
Cephalexin	250–500 mg every 6 hours	15–30 mg/kg/day in 4 doses	Crosses placenta	Enters breast milk	Cephalosporins are alternate choices for patients allergic to penicillins, although cross-hypersensitivity can occur. May be associated with higher failure rates compared to other drug classes.
Cefaclor	250–500 mg every 8 hours	20–40 mg/kg/day in 2–3 doses	Crosses placenta	Small amount present	
Cefpodoxime proxetil	100 mg every 12 hours	10 mg/kg/day in 2 doses	Crosses placenta	Variable amounts; milk = 0–16% of serum	
Cefdinir	300 mg every 12 hours or 600 mg every 24 hours	14 mg/kg/day in 1 or 2 doses	Crosses placenta	Not detectable after single 600 mg dose	
Norfloxacin[d]	400 mg every 12 hours	Avoid	Arthropathy in immature animals	Unknown	Avoid antacids, divalent and trivalent cations, and sucralfate. Monitor INR in patients on warfarin. May cause dizziness.[e]
Ciprofloxacin[d]	250–500 mg every 12 hours	Avoid	Arthropathy in immature animals	Unknown	Alternate choice for patients allergic to β-lactams.[e] Useful for pseudomonal infection.
Levofloxacin	250 mg every 24 hours	Avoid	Arthropathy in immature animals	Milk = 100% of serum[c]	
Nitrofurantoin	100 mg every 12 hours (e.g., Macrobid) 50–100 mg every 6 hours (e.g., Macrodantin)	5–7 mg/kg/day in 2–4 doses	Hemolytic anemia in newborn	Variable amounts; not detectable up to 30%; may cause hemolysis in G6PD-deficient baby	Alternate choice. To be taken with food or milk. May cause brown or rust-yellow discoloration of urine.
Sulfamethoxazole (SMX)	1 g every 12 hours	60 mg/kg/day in 2 doses	Crosses placenta; displacement of	Enters breast milk;	Alters bowel flora to favor

			bilirubin may lead to hyperbilirubinemia and kernicterus, avoid after 32 weeks of gestation; teratogenic in some animal studies	displacement of bilirubin may lead to neonatal jaundice; may cause hemolysis in G6PD-deficient baby	resistant organisms. To be taken on an empty stomach with a full glass of water. Photosensitivity may occur.

Trimethoprim (TMP)	100 mg every 12 hours		Crosses placenta (cord) = 60%; (maternal) folate antagonism, avoid during first trimester; teratogenic in rats	(milk) >1 (serum)[c]	Alternate choice.
TMP–SMX	160 + 800 mg every 12 hours	10 mg/kg/day (TMP component in 2 doses)	Crosses placenta (cord) = 60%; (maternal) folate antagonism, avoid during first trimester; teratogenic in rats	(milk) >1 (serum)[c]	To be taken on an empty stomach with a full glass of water. Photosensitivity may occur. Monitor HIV-infected patients closely for development of adverse hematologic reactions.
					First-line agent for prostatitis.
Fosfomycin	3 g single dose	No data	Crosses placenta	Unknown	Recommended option for uncomplicated cystitis.

[a] Also see Chapter 49, Obstetric Drug Therapy.

[b] Includes unique patient consultation information in italics.

[c] Denotes drug concentration.

[d] May increase theophylline concentrations when given concurrently. Carefully monitor theophylline serum concentrations during quinolone use.

[e] Same comments apply to all fluoroquinolones.

G6PD, glucose-6-phosphate dehydrogenase; HIV, human immunodeficiency virus; TMP–SMX, trimethoprim–sulfamethoxazole.

Updated IDSA/ESMID guidelines for the treatment of acute uncomplicated cystitis and pyelonephritis were published in 2011, and serve as the basis for selection of antibiotics in V.Q. (Table 71-3).[20] The recommended first-line agents for treatment of this patient's uncomplicated cystitis include TMP–SMX, nitrofurantoin, and fosfomycin trometamol; a fourth recommended antibiotic, pivmecillinam, is not commercially available in the United States.

TMP–SMX is effective for therapy of uncomplicated cystitis.[1–3,20,53] Gram-positive and gram-negative organisms, with the notable exceptions of Enterococcus, P. aeruginosa, and anaerobes, are generally susceptible to TMP–SMX.[20],[54] Although TMP–SMX may appear active against enterococci in vitro, clinical efficacy against this pathogen does not always correlate well and is variable. Individually, trimethoprim and sulfamethoxazole are bacteriostatic, but in combination they are bactericidal against most urinary pathogens.[54] Furthermore, this combination is almost uniformly successful in the treatment of uncomplicated UTI, even against organisms that originally were resistant to either agent alone. Although rates of trimethoprim resistance have increased over the past several years,[20],[45–49,55] resistance rates remain relatively low in some geographic areas and trimethoprim alone may be effective in managing UTI in many patients.

The ratio of trimethoprim to sulfamethoxazole in the available tablet products is 1:5 (e.g., 80 mg trimethoprim and 400 mg sulfamethoxazole). This combination has been chosen to achieve peak serum concentrations of the two drugs that approximate a 1:20 ratio. This ratio is optimal for synergistic activity against most microorganisms, although the drugs remain synergistic and bactericidal in ratios ranging from 1:5 to 1:40 in vitro.[54],[56] Urinary concentrations of trimethoprim and sulfamethoxazole far exceed the minimum inhibitory concentrations (MIC) for most susceptible urinary pathogens. Therefore, good in-vitro activity, excellent clinical success which is similar to that of the fluoroquinolones and other alternative agents in susceptible strains, relatively low resistance rates among common pathogens, and low cost make TMP–SMX a reasonable choice in V.Q.[20] The 2011 IDSA/ESMID guidelines recommend TMP–SMX as an appropriate initial agent of choice in the treatment of acute, uncomplicated lower UTI in geographic areas where the incidence of TMP–SMX resistance among E. coli is less than 20%.[20],[57]

Nitrofurantoin is also recommended as an appropriate agent for empirical treatment of acute uncomplicated cystitis.[20] Nitrofurantoin is almost completely absorbed after oral administration, but it barely reaches detectable levels in the plasma because it is rapidly eliminated (half-life, 20 minutes) into the urine and bile; the resulting high urine levels are 50 to 250 mg/L and are well in excess of the MIC for most common pathogens causing UTI.[58] Food substantially decreases the rate of absorption, but it increases the total bioavailability of nitrofurantoin from both the macrocrystalline capsules and the microcrystalline tablets by about 40%. This effect lengthens the duration of therapeutic urine concentrations by about 2 hours.[58]

Nitrofurantoin has a spectrum of activity which includes E. coli, some strains of

Pseudomonas, S. saprophyticus, streptococci, and enterococci; on the other hand, Proteus, Enterobacter, and Klebsiella are more likely to be resistant (susceptibility <60%).[20,48,59] Nitrofurantoin does not significantly alter the fecal or introital flora, and the development of resistance in previously sensitive strains does not often occur.[20,60] In contrast to ampicillin, TMP–SMX, and other drugs with relatively high resistance rates, nitrofurantoin has maintained excellent activity against most uropathogens; susceptibility rates among E. coli currently range from 90% to 99% in most geographic areas.[20,45–49,59] Finally, nitrofurantoin has been shown in comparative clinical studies to be as effective as TMP–SMX, fluoroquinolones, or fosfomycin in the treatment of acute uncomplicated cystitis.[20] Nitrofurantoin is thus recommended in the most recent clinical guidelines as an appropriate choice for treatment of uncomplicated UTI in patients such as V.Q. (Table 71-3).[20]

Most practitioners in the United States have little experience with fosfomycin trometamol, but the drug has, nevertheless, been used quite successfully in the treatment of UTI in many other parts of the world.[20,44] Fosfomycin is a phosphonic acid derivative which has been shown to irreversibly block bacterial cell wall synthesis through inhibition of early cytoplasmic stages of peptidoglycan synthesis.[44,61] It has bactericidal activity against a broad range of gram-negative and gram-positive organisms including E. coli and other Enterobacteriaceae, Pseudomonas aeruginosa, and Enterococcus as well as many multidrug-resistant pathogens such as methicillin-resistant S. aureus, vancomycin-resistant enterococci, and ESBL-producing gram-negative bacilli.[20,44] Fosfomycin is approximately 40% absorbed after oral administration as granules marketed in a sachet form and is rapidly and almost completely excreted unchanged in the urine. Fosfomycin achieves mean urinary concentrations greater than 500 mg/L within 6 to 8 hours after administration and maintains concentrations greater than 100 mg/L for a duration of more than 26 hours after a single oral dose.[44,61] Single 3-g oral doses of fosfomycin are clinically as effective as trimethoprim and nitrofurantoin, although microbiological efficacy may be less.[20] Nevertheless, fosfomycin is currently recommended for treatment of acute uncomplicated cystitis in the 2011 IDSA/ESMID guidelines (Table 71-3).[20] It should be noted that although fosfomycin is commercially available in the United States, it is substantially more expensive than either TMP–SMX or nitrofurantoin.

Table 71-3

Summary of Evidence-Based Recommendations for Treatment of Acute Uncomplicated Cystitis and Pyelonephritis[20]

Recommendations	**Recommendation Grades[a]**
Cystitis	
Preferred Agents	
Nitrofurantoin monohydrate/macrocrystals 100 mg PO twice daily × 5 days	A-1
TMP–SMX 160/800 mg (1 double-strength tablet) PO twice daily × 3 days	A-1
Trimethoprim 100 mg PO twice daily × 3 days is considered equivalent to TMP–SMX and is the preferred agent in some regions	A-3
Fosfomycin trometamol 3 g PO × 1 dose	A-1, but appears to have inferior microbiological efficacy compared with standard short-course therapies with agents such as trimethoprim or nitrofurantoin
Pivmecillinam 400 mg PO twice daily × 3–7 days (not commercially available in the United States)	A-1, but may have inferior efficacy compared with other available therapies
Resistance Considerations	
A specific antibiotic is no longer recommended for empirical treatment when the prevalence of resistance is ≥20%	B-3 for TMP–SMX No recommendation for other agents
Alternative agents	
fluoroquinolones	
Fluoroquinolones (ciprofloxacin or levofloxacin) PO × 3 days are highly efficacious for acute cystitis	A-1
Fluoroquinolones should be reserved for other important clinical uses because of propensity for collateral damage	A-3
β-LACTAMS	
β-Lactams (including amoxicillin–clavulanate, cefdinir, cefaclor, and cefpodoxime–proxetil) PO × 3–7 days are appropriate when other recommended agents cannot be used	B-1
Other β-lactams such as cephalexin are less well studied but may also be appropriate in certain settings	B-3
β-Lactams generally have inferior efficacy and more adverse effects compared with other antimicrobials for UTI	B-1
Pyelonephritis	
All Patients	
Urine culture and susceptibility testing should be performed and initial empirical antibiotic therapy tailored appropriately based on results	A-3
Outpatient Treatment	
fluoroquinolones	
Ciprofloxacin 500 mg PO twice daily × 7 days, ± an initial IV dose of ciprofloxacin 400 mg, a long-acting parenteral cephalosporin (e.g., ceftriaxone 1 g) or a consolidated 24-hour dose of an aminoglycoside (e.g., gentamicin 5–7 mg/kg)	A-1

Ciprofloxacin 1,000 mg extended release tablet PO once daily × 7 days, or levofloxacin 750 mg PO once daily × 5 days	B-2
If the local prevalence of fluoroquinolone resistance among uropathogens is >10%, an initial one-time IV dose of a long-acting parenteral cephalosporin or a consolidated 24-hour dose of an aminoglycoside should be administered	B-3
Alternative agents	
TMP–SMX 160/800 mg (1 double-strength tablet) PO twice daily × 14 days	A-1
If TMP–SMX susceptibility is not known, an initial IV dose of a long-acting parenteral cephalosporin or a consolidated 24-hour dose of an aminoglycoside should be administered	B-2 for a cephalosporin B-3 for an aminoglycoside
Oral β-lactams × 10–14 days are less effective than other available agents	B-3
If an oral β-lactam is used, an initial IV dose of a long-acting parenteral cephalosporin or a consolidated 24-hour dose of an aminoglycoside should be administered	B-2 for a cephalosporin B-3 for an aminoglycoside
Hospitalized Patients	
One of the following antibiotic options may be used initially, based on local resistance data and tailored based on susceptibility results: IV fluoroquinolone; IV aminoglycoside ± IV ampicillin; extended-spectrum IV cephalosporin or extended-spectrum IV penicillin ± aminoglycoside; or IV carbapenem.	B-3

[a]Strength of recommendations: A, B, C = good, moderate, and poor evidence to support recommendation for or against use, respectively.

Quality of evidence: 1 = evidence from ≥1 properly randomized, controlled trial; 2 = evidence from ≥1 well-designed clinical trial without randomization, from cohort or case-control analytic studies, from multiple time series, or from dramatic results from uncontrolled experiments; 3 = evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert committees.

IV, intravenous; PO, orally; TMP–SMX, trimethoprim–sulfamethoxazole; UTI, urinary tract infection.

Alternative agents for the treatment of UTI in V.Q. include the fluoroquinolones and various oral β-lactam antibiotics.[20] The fluoroquinolones remain highly effective in the treatment of UTI. However, increasing rates of resistance among common uropathogens and the potential for significant collateral effects on normal flora leading to complications such as Clostridium difficile infection have led to recent recommendations that the fluoroquinolones not be routinely used as preferred agents in the treatment of uncomplicated UTI such as that present in V.Q. [20] Further details regarding the use of fluoroquinolones for UTI are discussed in Case 71-2.

Amoxicillin–clavulanate and several oral cephalosporins have been studied for the treatment of uncomplicated UTI; these studies have shown the β-lactams to be generally comparable to TMP–SMX, but less clinically or microbiologically effective than the fluoroquinolones.[20] β-lactams require longer durations of treatment (see Case 71-1, Question 4), which makes them less attractive from the standpoint of ensuring patient adherence and may also predispose to higher rates of drug-related adverse effects.[20] Finally, these relatively broad-spectrum agents may be associated with more frequent emergence of bacterial resistance, including ESBL-producing gram-negative bacilli.[20] Thus, the β-lactam antibiotics (with the exception of pivmecillinam) are currently only recommended for empirical treatment of uncomplicated cystitis when none of the other agents previously discussed can be used (Table 71-3).[20] Of note, ampicillin and amoxicillin are specifically discouraged for empirical treatment of UTI because of the high resistance rates previously noted.[20]

V.Q. could be appropriately treated with either TMP–SMX, nitrofurantoin, or fosfomycin. She has no apparent patient characteristics that would favor the use of one agent over another. In this case, the most important factor to consider would be local antibiotic susceptibilities among community-acquired uropathogens, particularly E. coli. Local costs and availability of the different options would also be important to consider in V.Q.

Note that the current IDSA/ESMID guidelines do not apply to the empirical selection of antibiotics for complicated UTI. Complicated infections are often associated with more difficult pathogens (e.g., P. aeruginosa) and increased risk of antibiotic resistance; fluoroquinolones are therefore considered preferred agents for initial treatment of complicated UTI with subsequent antibiotic therapy guided by the results of C&S testing.[1–3,5,24]

DURATION OF ANTIBIOTIC THERAPY

CASE 71-1, QUESTION 4: V.Q. is started on TMP–SMX for treatment of her infection. What would be the preferred duration of therapy of antibiotic therapy for V.Q.?

Outpatients with acute, uncomplicated UTI can be treated successfully with a traditional 7- to 14-day course of oral medications, a shorter 3- to 5-day course of therapy, or with single-dose therapy.[1–3,5,20,62] The traditional 7- to 14-day course of antibiotic therapy now is considered excessive for most patients with uncomplicated infections and is seldom used.[1–3,5,20,62] A 3- to 5-day antibiotic treatment regimen is just as effective as a 10-day regimen in achieving clinical cures and eradicating urinary tract organisms, although this is somewhat antibiotic class–specific.[1–3,5,20,62] TMP–SMX is recommended as the preferred agent for 3-day treatment regimens; the fluoroquinolones may also be used in this shorter duration (Table 71-3).[20] A 5-day course of nitrofurantoin is as effective as a 3-day course of TMP–SMX for acute uncomplicated cystitis, and nitrofurantoin is thus currently recommended as a 5-day regimen.[20],[63] β-Lactam antibiotics are more appropriately reserved for longer treatment courses of 3 to 7 days.[5],[20] Longer treatment courses are also used in cases of treatment failure after regimens of shorter duration, as well as in the treatment of complicated UTI where longer courses of therapy (7–14 days) are associated with higher clinical success rates and improved outcomes.[1–3,24]

Even a single dose of an antibiotic may be effective. Bacteria disappear from the urine within hours after antibacterial therapy has been initiated.[20] This, coupled with the urinary bladder’s ability

---

to defend itself through micturition, acidification, and inherent antibacterial activity, gives theoretic support to the clinical evidence that a large single dose of an antibiotic can eradicate a UTI. Fosfomycin trometamol is a perfect example of this principle: very high urinary concentrations of this bactericidal agent are maintained for more than 24 hours after a single 3-g oral dose and contribute to the favorable clinical efficacy observed in comparative trials.[20],[44],[61]

Although not recommended in the current guidelines, single doses of antibiotics other than fosfomycin are also occasionally used in treating acute, lower UTI in young women.[5],[8],[20] Commonly used regimens are TMP–SMX (two or three double-strength tablets), trimethoprim 400 mg, amoxicillin–clavulanate 500 mg, amoxicillin 3 g, ampicillin 3.5 g, nitrofurantoin 200 mg, ciprofloxacin 500 mg, and norfloxacin 400 mg.[1],[20] Again, choice of a specific agent should be based on local susceptibility patterns, patient allergies, and relative drug costs. Female patients with history or clinical presentation suggestive of complicated infection (e.g., systemic manifestations of infection, renal disease, anatomic abnormalities of the urinary tract, diabetes mellitus, pregnancy), a history of antibiotic resistance, or a history of relapse after single-dose therapy should not receive single-dose regimens. Single-dose therapy is also not appropriate for male patients with UTI. Because V.Q. does not have any of these contraindications, she could theoretically receive single-dose therapy with an appropriate agent.

The advantages of single-dose treatment of UTI include improved compliance, reduced cost, proven efficacy in a defined population of patients (i.e., young women with acute, uncomplicated lower UTI), minimal side effects, and a potentially decreased incidence of bacterial resistance associated with antibiotic overuse. However, several concerns also exist regarding single-dose therapy.[5],[8],[20] First, sample sizes in most comparative studies were relatively small. Consequently, it is difficult to determine whether differences in effectiveness or incidence of side effects between single-dose and multiple-dose therapy are clinically significant. Meta-analysis of studies comparing either single-dose or 3-day regimens with TMP–SMX therapy has demonstrated that single-dose therapy is significantly less effective in eradicating bacteriuria than regimens of ≥5 days (83% vs. 93%, respectively, $p < 0.001$) or ≥7 days in duration (87% vs. 94%, respectively; $p = 0.014$).[20],[53],[62] As discussed in Case 71-1, Question 3, reduced microbiological efficacy was also observed with single-dose fosfomycin.[20] Although fewer studies have directly compared single-dose versus 3-day therapies, numerous studies have shown that 3-day courses are as effective as courses of longer duration.[20],[62] Finally, single-dose therapies have been associated with higher rates of recurrence compared with therapies of longer duration.[5] A 3-day on 5-day course of therapy is therefore currently recommended by the IDSA/ESMID for uncomplicated cystitis; a large single dose of fosfomycin is the sole single-dose regimen endorsed by the guidelines.[18]

Based on the preceding information, and according to current guidelines, a 3-day course of TMP–SMX, a 5-day course of nitrofurantoin, or a single dose of fosfomycin would be most appropriate for treatment of V.Q.'s infection (Table 71-3).[20]

When using short-course regimens, it is important to counsel the patient that the clinical signs and symptoms of infection may often not be completely resolved for 2 to 3 days after initiation of therapy. Therefore, symptoms that persist for a short while after beginning therapy (or actually completing therapy, in the case of single-dose regimens) are not necessarily indicative of treatment failure.

PHENAZOPYRIDINE

CASE 71-1, QUESTION 5: Along with TMP–SMX, phenazopyridine is also prescribed because of V.Q.'s complaints of significant dysuria. Is phenazopyridine appropriate for this patient?

Phenazopyridine, a urinary tract analgesic, occasionally is prescribed alone or along with an antibacterial agent for the symptomatic relief of dysuria. Although phenazopyridine at a dose of 200 mg orally three times a day may relieve dysuria, it is ineffective in the actual eradication of true UTI. Phenazopyridine plus an antibiotic is not any better than an antibiotic alone; therefore, the drug is not likely of significant value in V.Q. and should not be routinely recommended. However, although most patients have resolution of symptoms within 24 to 48 hours after beginning therapy, certain patients with severe dysuria or delayed response to antibiotic therapy may benefit symptomatically from a short trial (1–2 days) of phenazopyridine.[5] The need for, and duration of, analgesic therapy must be individualized.

Phenazopyridine is an azo dye and may discolor the urine to an orange–red, orange–brown, or red color that can stain clothes. Other adverse effects of phenazopyridine occur after acute overdose, or as a result of accumulation in older patients or in patients with decreased renal function who take the drug chronically. In vivo, about 50% of phenazopyridine is metabolized to aniline, which can cause methemoglobinemia and hemolytic anemia. Hemolytic anemia associated with phenazopyridine occurs primarily in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency.[64] Cases of reversible acute renal failure and allergic hepatitis have also been rarely reported after brief exposure to phenazopyridine.[64]

INTERPRETATION OF URINE CULTURE AND SUSCEPTIBILITY TEST RESULTS

CASE 71-1, QUESTION 6: Two days after V.Q. begins treatment for her infection with TMP–SMX, results of the C&S studies become available and reveal greater than 10^5 bacteria per milliliter of P. mirabilis, which is susceptible to ampicillin, amoxicillin–clavulanate, cephalosporins, and gentamicin. The Proteus is intermediately sensitive to nitrofurantoin, and it is resistant to TMP–SMX and ciprofloxacin. V.Q. reports that she is symptomatically better since starting antibiotic therapy and that her dysuria and bladder pain are now almost completely resolved. How should these test results be interpreted? Is a change in V.Q.'s antibiotic therapy necessary?

Most women with either lower or upper UTI have greater than 10^5 bacterial colonies/mL of urine. However, a major revision in the diagnostic criteria for symptomatic UTI has been the abandonment of the absolute requirement for growth of $\geq 10^5$ bacterial colonies/mL of urine. The criterion of greater than or equal to 100 bacteria/mL results in excellent sensitivity and specificity in correctly diagnosing and treating women with symptomatic infection.[13] This same criterion should also be applied to lower UTI when S. saprophyticus is isolated, because UTIs caused by this pathogen often are associated with low urine bacterial colony counts, suboptimal growth on commonly used media, and negative findings on nitrite screening.

Mixed flora (more than two organisms) is unusual except in severely debilitated persons and other complicated infections. Thus, mixed flora in the setting of uncomplicated infection frequently suggests contamination, and a repeat specimen should be obtained.

Bacterial susceptibility to different antimicrobial drugs is usually determined by referencing interpretive criteria that correlate with achievable serum concentrations of those drugs. However, drugs useful in the treatment of UTI are excreted primarily by the kidney, and urine concentrations of these drugs may be 20 to 100 times greater than serum concentrations. Therefore, infections caused by organisms that are only intermediately susceptible, or even "resistant" to the tested concentration of antibacterial drug, might still be effectively treated with the high concentration of drug achieved in the urine.

Although in-vitro susceptibility testing is not always predictive of patient response to therapy of UTI, studies clearly show that patients infected with a resistant pathogen are at increased risk of treatment failure.[51],[57],[65],[66] Clinical response to infection occurred in only 24% to 61% of patients with organisms resistant to TMP–SMX compared with 83% to 92% of patients infected with susceptible organisms[51],[57],[65]; furthermore, patients infected with TMP–SMX-resistant pathogens were 17 times more likely to fail therapy compared with patients with susceptible strains.[67] Patients treated with TMP–SMX, who were infected with drug-resistant organisms, were also found to have longer median times to symptom resolution (14 vs. 7 days, $p = 0.0002$), more frequent return clinic visits within 1 week (36% vs. 6%, $p < 0.0001$), more frequent need for subsequent antibiotic therapy (36% vs. 4%, $p < 0.0001$), and higher rates of significant bacteriuria after 1 month (42% vs. 20%, $p = 0.04$).[65]

Although up to 75% of patients with resistant organisms may experience failure of TMP–SMX therapy, antimicrobial therapy is usually chosen empirically without the benefit of C&S testing results. Appropriateness of antibiotic therapy is, thus, usually judged according to subsequent clinical response. If the infecting organism is susceptible, the urine will usually be sterile for 24 to 48 hours. If a urine specimen collected 48 hours after initiation of therapy is not sterile and the patient has been taking the medication properly, the antibiotic may be inappropriate or the focus of infection may be deeper (e.g., pyelonephritis, abscess, obstruction). If the urine specimen is sterile and the patient is symptomatically improved, the appropriate antimicrobial is being used (regardless of susceptibility studies) and the full course of therapy should be completed. Because V.Q. reports significant improvement in her subjective symptoms, her 3-day course of TMP–SMX should be completed as originally ordered and V.Q. should be closely monitored for any evidence of relapse. A repeat C&S test should be performed in the event that V.Q. reports any new signs or symptoms which are consistent with antibiotic failure and relapse of her infection, and a different antibiotic should be selected for treatment at that time.

FLUOROQUINOLONE THERAPY

CASE 71-2

QUESTION 1: I.B., a 48-year-old woman, presents with a community-acquired UTI. She has a past medical history significant only for several previous episodes of UTI. A UA is ordered with the following results:

Appearance, straw-colored and turbid (normal, straw-colored and clear)
Specific gravity, 1.028 (normal, 1.002–1.028)
pH, 6.3 (normal, 5.5–7.0)
Glucose, ketones, and bilirubin, all negative (normal, all negative)
Blood and protein, both trace positive by dipstick (normal, both negative)
WBC, 10 to 15 cells/LPF (normal, 0–2 cells/LPF)
RBC, 5 to 10 cells/LPF (normal, 0–2 cells/LPF)
Bacteria, many (normal, 0 to rare)
Epithelial cells, 3 to 5 cells/LPF (normal, 0 to few cells/LPF)
Leukocyte esterase and nitrite tests by dipstick, both positive (normal, both negative)

Of note, I.B. has experienced a rash with TMP–SMX and a type I hypersensitivity reaction to penicillins in the past. What is the role of fluoroquinolones in the treatment of I.B.'s community-acquired UTI?

Several fluoroquinolones are indicated for the treatment of uncomplicated or complicated UTI; these include norfloxacin, ciprofloxacin, and levofloxacin. The fluoroquinolones are usually administered orally in the treatment of UTI and have excellent in-vitro activity against most gram-negative organisms, including P. aeruginosa.[68] They are also active in vitro against many gram-positive organisms including S. saprophyticus.[68] The activity of many fluoroquinolones in vitro is antagonized by urine (acidic pH, divalent cations); however, this is unlikely to be clinically significant because urine concentrations are several hundred-fold greater than serum levels.[68] A large number of clinical trials have demonstrated that fluoroquinolones are very effective in the treatment of acute uncomplicated UTI with efficacy rates typically greater than 90%.[20],[53]

Although the fluoroquinolones are as effective as TMP–SMX, nitrofurantoin, or β-lactams in treatment of uncomplicated UTI, they are no longer recommended as first-line empirical therapy because they are more expensive and provide no additional treatment benefits.[5],[8],[20],[53],[68] Concerns also exist regarding the overuse of fluoroquinolones and the promotion of drug resistance among community-acquired uropathogens. Resistance to fluoroquinolones among organisms causing acute uncomplicated UTI is usually less than 1% to 2%.[21] Fluoroquinolone resistance may, however, be more frequent in some geographic areas and in complicated infections[45–49,55]; recent studies have documented resistance to ciprofloxacin in 2% to 10% of acute uncomplicated infections, whereas it is 8% to 60% in complicated UTI.[20],[46–49,69] Furthermore, these quinolone-resistant strains often are resistant to multiple other antimicrobials.[46–49,69] Concerns also exist regarding the potential for fluoroquinolones to produce collateral effects on normal flora, these alterations leading to increased risk of infection because of methicillin-resistant S. aureus and C. difficile.[20]

Fluoroquinolones are recommended as appropriate alternatives for patients with allergies or other contraindications to the use of other first-line agents, or for patients infected with organisms resistant to multiple antibiotics, such as P. aeruginosa. Fluoroquinolones are appropriate initial therapy in geographic areas with greater than 20% resistance of E. coli to TMP–SMX[20]; however, many patients in such areas may be appropriately treated with nitrofurantoin or some other options (Table 71-3).[20] Finally, the fluoroquinolones are effective in treating patients with structural or functional abnormalities of the urinary tract and other complicated infections.[20],[68]

A fluoroquinolone may be considered for I.B. because she has experienced previous adverse reactions to penicillins and sulfonamides. However, nitrofurantoin or fosfomycin should be preferentially considered for I.B. based on current IDSA/ESMID recommendations.[20] If a fluoroquinolone was deemed appropriate for I.B. based on other unspecified factors such as availability, cost, or tolerability issues with other treatment options, the fluoroquinolones are similar in efficacy and the choice would be based on comparative costs and compliance considerations.[20] The duration of fluoroquinolone therapy in I.B. would be 3 days.[20]

NITROFURANTOIN-INDUCED ADVERSE EFFECTS

CASE 71-2, QUESTION 2: The decision is made to begin I.B. on nitrofurantoin rather than a fluoroquinolone. After beginning nitrofurantoin monohydrate 100 mg twice daily, she complains of nausea and gastrointestinal (GI) upset after the ingestion of each dose. I.B. had her nitrofurantoin prescription filled with nitrofurantoin monohydrate because it was the less expensive product at her local pharmacy. How can these GI effects be minimized in I.B.? What other important adverse effects are associated with nitrofurantoin?

Nausea is a common complication of nitrofurantoin therapy, and the patient's adherence with the prescribed regimen may be affected by this side effect. It is not known whether the mechanism by which nitrofurantoin produces nausea is central or local. Taking nitrofurantoin with food may reduce nausea either through serving as a buffer or slowing the rate of absorption and reducing peak concentrations

---

of the drug. Food, however, may also increase the bioavailability of nitrofurantoin. Slowing of absorption is particularly beneficial in decreasing the incidence of nausea and vomiting associated with the microcrystalline product.[59] Use of the macrocrystalline preparation may also reduce adverse effects through slowing rates of dissolution and absorption, and producing lower serum levels. A disadvantage of the macrocrystalline form is the cost, which may be 2 to 10 times that of the microcrystalline form, depending on the product source. Finally, because nausea and vomiting appear to be dose related and occur more frequently in small persons, reducing the daily dose of nitrofurantoin may also improve tolerability.[58],[59] However, the best-studied and clinically effective dose of nitrofurantoin is 100 mg twice daily[20],which I.B. is currently receiving. I.B. should remain on her current dose; taking the drug with food and/or switching to a macrocrystalline product should allow her to successfully finish her course of nitrofurantoin at the recommended dose.

Several hundred cases of nitrofurantoin-induced acute, subacute, or chronic pulmonary reactions have been reported.[70] Acute toxicity often manifests within several days of initiating the drug with a sudden flu-like syndrome consisting of fever, dyspnea, and cough; eosinophilia may also be present. The subacute form usually occurs after at least a month of exposure; symptoms include fever and dyspnea. The chronic form tends to be more insidious with milder dyspnea and low-grade fever. In all forms, rales are common and pulmonary infiltrates may be present on chest radiograph.[70] Discontinuation of nitrofurantoin results in complete symptomatic recovery after several weeks; however, permanent fibrotic changes may persist with chronic pulmonary reactions. Rechallenge with oral nitrofurantoin results in rapid reappearance of pulmonary symptoms in those who have had an acute reaction; the drug must therefore be avoided in patients with history of nitrofurantoin-induced pulmonary toxicity.[70]

Peripheral neuropathy may also occur during nitrofurantoin therapy and is characterized by symmetric dysesthesia and paresthesia in the distal extremities, which progresses in a central and ascending fashion.[58],[71] Neuropathy usually occurs within the first 60 days of chronic nitrofurantoin treatment and is rarely seen during shorter courses of therapy.[58],[71] Symptom severity is not dose-related and is generally reversible, although more severe cases may require up to several months to resolve completely. Renal failure is a risk factor for both neurotoxicity and pulmonary toxicity, but neuropathy has also been reported in patients with normal renal function.[58],[71]

FLUOROQUINOLONE USE IN PEDIATRIC INFECTIONS

CASE 71-3

QUESTION 1: C.S. is a 2-year-old girl with a history of multiple recurrent UTIs caused by congenital urinary tract abnormalities that have not been corrected. She has had at least nine UTIs since birth and has received multiple courses of antibiotics, including ampicillin, amoxicillin, amoxicillin–clavulanate, and TMP–SMX. She has also been on chronic low-dose antibiotic prophylaxis with TMP–SMX. C.S. was brought to her pediatrician 48 hours ago with signs and symptoms consistent with a new UTI. Suprapubital aspiration was performed and urine samples sent for C&S testing at that time, and C.S. was empirically begun on amoxicillin–clavulanate pending laboratory test results. C&S results, however, are now available and show >10^5 colonies/mL of P. mirabilis. The organism is susceptible to ciprofloxacin, gentamicin, and ertapenem and resistant to ampicillin, trimethoprim, TMP–SMX, cephalexin, cefaclor, cefpodoxime, tetracycline, nitrofurantoin, and erythromycin. C.S. has not clinically improved while receiving empiric amoxicillin–clavulanate. What antibiotic therapy would be most appropriate for continued management of this acute infection in C.S.?

This case illustrates the serious dilemmas caused by antibiotic resistance among uropathogens. The pathogen isolated from C.S. is resistant to all commonly used, orally administered antibiotics that have been proved effective in the treatment of UTI in pediatric patients. Penicillins, cephalosporins, nitrofurantoin, and sulfonamides are frequently recommended for treatment of pediatric UTI; however, multiple past treatment regimens and chronic antibiotic prophylaxis make these agents less suitable for treatment of this new infection in C.S. Although in-vitro susceptibility testing does not accurately predict clinical response to therapy in all cases, the risk of treatment failure and poor patient outcome is significantly increased when agents to which isolates are resistant are administered.[57],[65] Alternative treatment is required; however, few desirable options exist for C.S.

The recommended duration of antibiotic therapy in C.S. would be at least 2 weeks for the treatment of this complicated and recurrent infection (refer to subsequent sections of this chapter). Although the organism isolated from C.S. is susceptible to gentamicin and this drug would be effective, parenteral (intramuscular or intravenous) administration would be required and the lengthy required treatment duration makes this far from ideal. Use of aminoglycosides would also be less desirable because of toxicity concerns. Although ertapenem would also likely be effective, there is relatively little clinical experience with this agent in the pediatric population and ertapenem would also require parenteral administration for the duration of the treatment regimen.

Fluoroquinolones are contraindicated in children and adolescents younger than 18 years of age because of concerns regarding potential musculoskeletal toxicities in juvenile populations. Although not approved for pediatric use, fluoroquinolones have been formally studied for febrile neutropenia, infectious gastroenteritis, otitis media, bacterial meningitis, and other uses in pediatric patients.[72–74] The use of fluoroquinolones has substantially increased in children and adolescents, most likely owing to resistance to other antimicrobials; approximately 520,000 prescriptions were written for patients younger than 18 years of age during 2002, of which nearly 3,000 prescriptions were for children younger than 2 years.[72] Several reviews summarized data related to the safety of fluoroquinolones in children. Although tendinopathy or other musculoskeletal toxicities have been recorded, these toxicities have been usually mild, reversible, and occurring at rates comparable to that seen in adults.[72–74] Based on currently available information and in consideration of antimicrobial resistance, the American Academy of Pediatrics has published recommendations regarding the use of fluoroquinolones in children and adolescents.[72] These indicate that fluoroquinolones may be considered in special circumstances including (a) infections caused by multidrug-resistant pathogens for which there are no other safe and effective alternatives and (b) times when parenteral therapy is not feasible and no other effective oral agent is available. Treatment of UTI caused by multidrug-resistant, gram-negative pathogens are specifically mentioned as a potentially appropriate use for fluoroquinolones in pediatric patients.[72]

Selection of a specific agent for the treatment of UTI in C.S. should be based on careful consideration of potential risks and benefits of available antibiotic options. The feasibility, risks, expenses, and inconvenience associated with prolonged (≥2 weeks) parenteral administration of an aminoglycoside or carbapenem are problematic; however, the ease of oral fluoroquinolone administration must be carefully balanced against the possible risks of using these agents in C.S. Clearly, no antibiotic of choice exists for treatment of C.S. and both the providers and the child's parents must be involved in development of an acceptable and well-informed treatment plan.

TREATMENT OF LOWER-TRACT INFECTION IN RENAL FAILURE

CASE 71-4

QUESTION 1: K.M., a 55-year-old man with a history of hypertension and chronic renal failure, experiences a UTI. His creatinine clearance, determined from a recent 24-hour urine collection, is 20 mL/minute. What antimicrobial agent should be prescribed?

The major problem in treating UTI in patients with renal failure is how to achieve adequate urine concentrations of the drug without causing systemic toxicity. The ideal drug would be (a) inherently nontoxic, even at high serum concentrations, making dosage adjustments unnecessary; (b) excreted unchanged in the urine (i.e., not metabolized); and (c) eliminated by renal tubular secretion rather than glomerular filtration. Because renal tubular secretion remains active in all but the most severe cases of renal failure, antibiotics eliminated by this mechanism would reach adequate urinary levels; however, no such ideal drug exists.

Nitrofurantoin and many sulfonamides are substantially metabolized by the liver and generally produce low urine levels in uremic patients. The aminoglycosides are eliminated almost exclusively by the kidneys, but uremic patients are at high risk of drug-induced toxicities and alternative agents are usually recommended. Penicillins, cephalosporins, and trimethoprim are partially metabolized by the liver but are also eliminated by the kidney to a significant extent. These agents are suitable for use in renal failure according to the criteria described above. Certain fluoroquinolones, specifically ciprofloxacin and levofloxacin, are highly excreted in the urine through a combination of filtration and tubular secretion and reach extremely high urinary concentrations. These agents are also considered safe and effective in the treatment of UTI in patients with renal failure.

Acute Pyelonephritis

SIGNS AND SYMPTOMS

CASE 71-5

QUESTION 1: L.B., a 45-year-old woman with type 1 diabetes mellitus, comes to the emergency department complaining of severe nausea, frequent vomiting, frequent urination, fever, shaking chills, and flank pain. Positive physical findings include a temperature of 103°F, a pulse of 110 beats/minute, blood pressure of 90/60 mm Hg, and CVA tenderness. A Gram stain of L.B.'s urine reveals gram-negative rods, and a UA demonstrates glucosuria, macroscopic hematuria, 20 to 25 WBC/LPF, numerous bacteria, and WBC casts. She also has a blood sugar level of 400 mg/dL. L.B. is admitted to the hospital with a diagnosis of acute bacterial pyelonephritis, and routine laboratory tests including a blood chemistry profile and complete blood count with differential, and specimens of urine and blood for C&S are ordered. L.B. is started on intravenous (IV) normal saline, ampicillin 1 g IV every 6 hours, and a sliding-scale schedule of regular insulin based on every 6-hour blood sugars. Which signs and symptoms in L.B. are consistent with pyelonephritis?

It is not always possible to differentiate clinically between upper and lower urinary tract infections. Symptoms common in lower UTI often are the only positive findings in upper UTI (i.e., subclinical pyelonephritis).[1–5,75] L.B., however, does manifest signs and symptoms of systemic infection consistent with acute bacterial pyelonephritis, including tachycardia, hypotension, fever, nausea and vomiting, shaking chills, flank pain, CVA tenderness, hematuria, and WBC casts. In addition, her diabetes may predispose her to various renal infections, including pyelonephritis, possibly because diabetic patients have altered antibacterial defense mechanisms.[2–5,75]

Treatment

TRIAGE FOR HOSPITALIZATION

CASE 71-5, QUESTION 2: Why was L.B. hospitalized?

Most patients with clinical pyelonephritis have relatively mild infection and usually can be treated as outpatients. The need for hospitalization often is determined by the patient's social situation and ability to maintain an adequate fluid intake and tolerate oral medications.[2–5,8,20] Patients who experience significant nausea and/or vomiting may not be able to maintain adequate hydration and thus may be at higher risk for cardiovascular complications of infection. Such patients may also require parenteral therapy initially in order to guarantee adequate initial antibiotic therapy. Finally, patients such as L.B. with diabetes should be hospitalized because acute pyelonephritis may predispose her to diabetic ketoacidosis.

Although blood cultures are usually obtained in patients with moderate-to-severe pyelonephritis, one study found that blood cultures were of low yield in the setting of acute uncomplicated pyelonephritis; they rarely provided any additional information not already obtained from the urine culture and were not helpful in the clinical management of such cases.[76] Blood cultures may be positive in up to 25% of patients with severe or complicated pyelonephritis, however, and they are still recommended for hospitalized patients such as L.B.[2–5,75,76]

ANTIMICROBIAL CHOICE FOR PYELONEPHRITIS

CASE 71-5, QUESTION 3: Was ampicillin appropriate treatment for L.B.?

Ampicillin is not an appropriate choice for L.B. because diabetic patients (and patients treated with corticosteroids) are susceptible to colonization with unusual or more resistant organisms. As with lower tract UTI, pyelonephritis is often classified as uncomplicated or complicated. L.B.'s infection would be classified as a complicated infection because of her underlying diabetes.[2–5,8,20,75]

E. coli remains the predominant pathogen in complicated pyelonephritis, but other gram-negative organisms (e.g., Klebsiella, Proteus, Pseudomonas) are found frequently.[2–5,8] Because L.B. is acutely ill and has gram-negative organisms in her urine, she should be treated with an antibiotic that has a better spectrum of activity against gram-negative organisms. Because of high rates of ampicillin resistance among common uropathogens, ampicillin and amoxicillin are inappropriate for the empirical therapy of UTI, including pyelonephritis.[20] Current IDSA/ESMID recommendations for the initial oral management of acute pyelonephritis are shown in Table 71-3. Because L.B. is to be hospitalized, broad-spectrum antibiotics appropriate for initial therapy would include parenteral third-generation cephalosporins (e.g., ceftriaxone), IV fluoroquinolones (e.g., ciprofloxacin, levofloxacin), extended-spectrum penicillins, such as piperacillin–tazobactam, or carbapenems.[2–5,8,20] Aminoglycosides may be used empirically as either monotherapy or in combination with various β-lactams: in combination with ampicillin to provide better activity against suspected enterococci, or together with cephalosporins or piperacillin–tazobactam to provide enhanced gram-negative activity.[20] The choice of a specific regimen is based on local susceptibility patterns and should be tailored as needed on the basis of C&S test results.[20] It is not always necessary to initially treat patients with antipseudomonal therapy; thus, agents such as ceftriaxone with relatively less activity against Pseudomonas are often appropriate as initial therapy in patients such as L.B.[4,8,20] Because most hospital laboratories can report C&S results within 48 hours, these antibiotics can be replaced with more specific ones if appropriate.

SERUM VERSUS URINE CONCENTRATIONS

CASE 71-5, QUESTION 4: Is it necessary to achieve bactericidal concentrations of antimicrobials in the serum, or are high urinary concentrations adequate for L.B.? How long should she be treated? How should therapeutic success be determined?

In patients with pyelonephritis and infection of the renal parenchyma, adequate tissue concentrations of antimicrobial agents are needed. Therefore, antibiotics that achieve bactericidal concentrations in serum and kidney tissues as well as in the urine should be selected.[20,77] Patients requiring hospitalization should be treated with parenteral antibiotics until fluids can be taken orally and the patient is symptomatically improved and afebrile for 24 to 48 hours.[2–5] This should be followed with a course of oral antibiotics for a total duration of antimicrobial therapy of approximately 14 days; less severe infections not requiring hospitalization are usually treated with 7- to 14-day courses, depending on the specific agent chosen.[20] Although it is customary to observe the patient in the hospital for 24 hours after switching from parenteral to oral antibiotics before discharge, this is probably of limited benefit.[2–5,8] Specimens for C&S testing should be obtained on the second day of therapy (to rule out treatment failure), 2 to 3 weeks after the completion of therapy, and again at 3 months.[1,4]

For patients who have relapsed after 14 days, retreatment for 6 weeks usually is curative. There have been reports of successful retreatment of relapsed infection with only 5 days of treatment[76]; however, longer courses are recommended.[4,8,76]

ORAL THERAPY FOR PYELONEPHRITIS

CASE 71-5, QUESTION 5: Would oral therapy have been appropriate for the initial treatment of acute pyelonephritis in L.B.?

Patients with mild, acute pyelonephritis (no nausea, vomiting, or signs of sepsis) can be treated with oral antibiotics such as fluoroquinolones for 5 to 7 days, or with TMP–SMX for 14 days.[2–5,20] Oral fluoroquinolones are preferred agents for initial empirical therapy of acute pyelonephritis in patients not requiring hospitalization because of lower rates of resistance among common uropathogens compared to TMP–SMX, and higher rates of clinical and microbiological efficacy compared to β-lactams.[20] Fluoroquinolones may be particularly useful for patients potentially infected with resistant organisms because of their excellent in-vitro activity against gram-negative organisms and high kidney tissue concentrations (2-fold to 10-fold greater than serum).[68] However, fluoroquinolone resistance and risk of inappropriate initial therapy may be more common in certain geographic areas. If fluoroquinolone resistance among E. coli exceeds 10%, treatment for acute pyelonephritis should be initiated with an intravenous dose of extended-spectrum cephalosporin or an aminoglycoside until C&S test results are known (Table 71-3).[20] Oral agents such as amoxicillin–clavulanate, cefuroxime, cefpodoxime proxetil, or cefdinir also can be used in this setting, but the most recent guidelines suggest that oral β-lactams are less effective than other available options and their use is somewhat discouraged as first-line treatment options.[20]

Patients such as L.B. with evidence of bacteremia (e.g., fever, shaking chills) or sepsis (e.g., hypotension) should be hospitalized and treated with parenteral antibiotics[4],[8],[20] (see Table 71-4). L.B.'s frequent vomiting and potential inability to be successfully treated with oral antibiotics would also make initial therapy with parenteral antibiotics more favorable. Although L.B. will be initially treated with parenteral antibiotics, early switch to oral therapy after as few as 1 to 4 days of treatment is recommended; clinical outcomes with oral antibiotics are similar to those achieved with continued parenteral therapy (i.e., 5 days or longer).[78]

RECURRENT URINARY TRACT INFECTIONS

Relapse versus Reinfection

CASE 71-6

QUESTION 1: T.W. is a 28-year-old woman with a history of recurrent UTIs who now exhibits a new E. coli UTI. Her last episode occurred 5 months previously. Her current infection is treated with TMP–SMX for 10 days. A repeat UA was scheduled for the completion of antibiotic therapy, but she canceled her appointment because she "felt fine." Twelve weeks later, she returns to the clinic with signs and symptoms of another UTI. The only other medication she has taken is an oral contraceptive. Why would C&S testing of a urine sample be especially useful at this time?

Recurrent infections develop in approximately 20% to 30% of women with acute cystitis.[3,5,34,79,80] Repeat C&S data should help determine whether this infection represents a relapse or a reinfection. Relapse refers to a recurrence of bacteriuria caused by the same microorganism that was present before initial therapy. Most relapses occur within 1 to 2 weeks after the completion of therapy and are caused by persistence of the organism in the urinary tract. Relapses often are associated with an inadequately treated upper UTI (e.g. medication non-adherence), structural abnormalities of the urinary tract, or chronic bacterial prostatitis.[1,34,79,80]

Reinfection implies recurrence of bacteriuria with a different organism than was present before therapy. Reinfections can occur at any time during or after the completion of treatment, but most appear several weeks to several months later. Approximately 80% of recurrences are caused by reinfection.[1,34] Reinfection is generally caused by introital colonization with Enterobacteriaceae from the lower intestinal tract[1]; of these, E. coli is the most common. Certain E. coli strains have been shown to adhere to vaginal epithelial cells and, in women with recurrent UTI, adherence of these organisms to epithelial cells is increased.[26] Considering T.W. was symptom-free for 8 weeks suggests that this is a reinfection, rather than a relapse. Patients with reinfection should be investigated for modifiable predisposing factors such as use of a diaphragm with or without spermicides. Patients with frequent reinfections should also be evaluated for risk factors such as anatomical abnormalities, undiagnosed glucose intolerance or diabetes, or other factors.

Treatment for Reinfection

CASE 71-6, QUESTION 2: Pending the C&S test results, what therapy should be instituted in T.W.?

T.W. has a history of recurrent infections and now probably has a reinfection. Because reinfection is not caused by failure of previous therapy, TMP–SMX may be a reasonable choice once again. The probability that a resistant organism will be responsible for the infection increases when the interval between infectious episodes is short. If several months elapse between each episode of antimicrobial therapy, normal fecal bacterial flora become reestablished and the risk of infection with resistant pathogens is reduced.

Table 71-4

Parenteral Antimicrobial Agents Commonly Used in the Treatment of Urinary Tract Infections

		Average Adult	Usual	

Class	Drug	Daily Dose		Dosage Interval[a]	Comments
		UTI	Sepsis		
Penicillins	Ampicillin	2–4 g	8 g	Every 4–6 hours	Use should be based on local susceptibility patterns.
	Ampicillin–sulbactam	6 g	12 g	Every 6 hours	
	Piperacillin–tazobactam	9 g	18 g	Every 4–6 hours	
First-generation cephalosporins	Cefazolin	1.5–3 g	6 g	Every 8–12 hours	More effective than second- or third-generation cephalosporins against gram-positive organisms.
Second-generation cephalosporins	Cefoxitin	3–4 g	8 g	Every 4–8 hours	Intermediate between first- and third-generation cephalosporins against gram-negative organisms.
	Cefuroxime	2.25 g	4.5 g	Every 8 hours	
Third-generation cephalosporins	Cefotaxime	3–4 g	8 g	Every 6–8 hours	Better coverage than first- and second-generation cephalosporins against gram-negative organisms. Ceftazidime and cefepime are most effective against Pseudomonas. All generations of cephalosporins are ineffective against Enterococcus faecalis and methicillin-resistant staphylococci.
	Ceftriaxone	1 g	2 g	Every 12–24 hours	
	Ceftazidime	1.5–3 g	6 g	Every 8–12 hours	
Fourth-generation cephalosporins	Cefepime	1–2 g	4 g	Every 12 hours	Ceftaroline has activity against methicillin-resistant staphylococci.
	Ceftaroline	0.6	0.6 g	Every 12 hours	
Carbapenems	Imipenem–cilastatin	1 g	2 g	Every 6 hours	The most broad-spectrum coverage of any antibiotics listed. Ertapenem not active against Pseudomonas. Resistance may develop especially with Pseudomonas. Toxic in some pregnant animals.
	Meropenem	1.5–3 g	3 g	Every 8 hours	
	Ertapenem	0.5–1 g	1 g	Every 24 hours	
Monobactam	Aztreonam	1–2 g	6–8 g	Every 8–12 hours	Active against gram-negative aerobic pathogens, including Pseudomonas sp.
Aminoglycosides	Gentamicin	3 mg/kg	5–7 mg/kg	Every 24 hours	Potent against gram-negative bacteria including Pseudomonas. Associated with possible eighth nerve toxicity in the fetus. Amikacin should be reserved for multiresistant bacteria.
	Tobramycin	3 mg/kg	5–7 mg/kg	Every 24 hours	
	Amikacin	7.5 mg/kg	15–20 mg/kg	Every 24 hours	
Quinolones	Ciprofloxacin	400–800	800 mg	Every 12	Use for resistant organisms. Change

		mg		hours	to oral Therapy when indicated.
	Levofloxacin	250–500 mg	500–750 mg	Every 24 hours	

[a] Assuming normal renal function. Dose adjustments need to be made in patients with compromised renal function (see Chapter 62, Principles of Infectious Diseases)

UTI, urinary tract infection.

The alteration of fecal flora caused by the sulfonamides makes these drugs poor choices for repeated use in cases of frequent reinfection, especially when C&S results are unknown. The development of bacterial resistance also may limit the usefulness of these agents for chronic antimicrobial therapy.[20,34,79,80] However, because her most recent infection was 12 weeks ago and the UTI prior to that was 5 months earlier, TMP–SMX would again be a reasonable choice at this time.

CASE 71-6, QUESTION 3: If T.W. exhibited an adverse reaction to TMP–SMX, what are some other therapeutic alternatives?

Nitrofurantoin is highly effective against E. coli with relatively low rates of resistance (<10%) in most geographic areas. It does not significantly alter the fecal or introital flora, and the development of resistance in previously sensitive strains does not often occur.[20,60,81] Therefore, it is generally a useful agent for the treatment of recurrent E. coli, S. saprophyticus, and Enterococcus infections.[20]

The fluoroquinolones also are useful in this setting, especially in geographic areas with high rates of TMP–SMX resistance.[34,78] Their widespread use should not be encouraged for reinfections as in T.W. in light of their high cost and concern regarding selection of resistant organisms.[20,34,80] Cephalosporins (e.g., cefuroxime, cefpodoxime proxetil) and trimethoprim have also been recommended as alternative agents in this setting.[3,79,80]

Antibiotic Selection for Treatment of Relapse

CASE 71-6, QUESTION 4: Greater than 10^5 bacteria per milliliter of P. mirabilis, sensitive to ampicillin and TMP–SMX, are cultured from T.W.'s urine. One week after completing her second course of TMP–SMX therapy, signs and symptoms of a UTI again appear. Pending C&S results, TMP–SMX is again prescribed. Is this still a reasonable medication for T.W. at this time?

Because the P. mirabilis cultured during the last recurrence was still susceptible to TMP–SMX, this agent would again be a reasonable choice until C&S test results are obtained. Alternatively, use of a different agent (e.g., nitrofurantoin, fluoroquinolone) could be considered because the relapse occurred within 1 week of completing the previous treatment and resistance may have developed.[5],[34],[80] Additional reasons for treatment failure, including failure to adhere to previously prescribed medication regimens, should also be investigated in patients with apparent recurrent infections.

CASE 71-6, QUESTION 5: How long should antibiotic therapy be continued in T.W. for her relapsed infection?

The duration of therapy for relapsing infections usually is 14 days. In patients who relapse after a second 2-week course of therapy, treatment for 6 weeks should be instituted.[1–3,34] If relapse occurs after a 6-week course, some experts recommend longer courses of 6 months to 1 year.[1–3] These prolonged courses should be reserved for children, adults who have continuous symptoms, or adults who are at high risk for experiencing progressive renal damage. Asymptomatic adults without evidence of obstruction should not receive these longer courses. T.W. should be treated for at least 2 weeks and perhaps as long as 6 weeks.[34],[80]

CASE 71-6, QUESTION 6: Although T.W. tolerated TMP–SMX well during her previous treatment, on this occasion she experiences significant nausea and vomiting after taking the medication. Would trimethoprim alone be an appropriate substitute for TMP–SMX in the treatment of T.W.'s infection?

Trimethoprim alone and in combination with sulfamethoxazole is active in vitro against many of the Enterobacteriaceae associated with UTI and is an effective alternative to TMP–SMX in the management of both acute and chronic UTI.[1–3,5] It would be especially appropriate for T.W. because GI intolerance to TMP–SMX is most commonly attributed to the sulfamethoxazole component, and trimethoprim is associated with a lower incidence of side effects. Some concern exists for the potential development of resistant organisms, but studies using trimethoprim alone have failed to demonstrate a significant increase in bacterial resistance.[79],[80] Trimethoprim is used for the treatment of acute, uncomplicated UTI in a dosage of 200 mg/day.

Chronic Prophylaxis

CASE 71-6, QUESTION 7: T.W. was treated successfully with trimethoprim for 6 weeks. Is prophylactic antimicrobial therapy indicated? If so, how long should it be continued?

Cases of chronic UTI in adult patients may be managed by treating each recurrent infection with an appropriate antibacterial drug or by administering chronic, low-dose prophylactic therapy. The frequency of urinary infections probably is the main determinant of whether chronic suppressive therapy should be used, because repeated treatment of recurrent infections eventually will result in a decreased incidence of subsequent infections.[1],[34],[80],[82] Long-term prophylactic therapy clearly reduces the frequency of symptomatic infections in nearly all patients.[15],[34],[80],[82] From a cost-effectiveness standpoint, women having more than one episode of cystitis per year may benefit from antimicrobial prophylaxis.[79] For women with three or more episodes of cystitis per year, prophylaxis clearly is more cost-effective than treating individual infections. Therefore, it is recommended that chronic antimicrobial prophylaxis may be considered in any adult patient with two or more episodes of UTI per year.[2],[34],[80]

The duration of prophylactic therapy is also determined by the frequency of infection. Women with three or more UTIs in the 12 months before a 6-month course of antimicrobial prophylaxis have a significantly higher recurrence rate (75%) in the 6 months after prophylaxis than women who have had only two infections in the 12 months before prophylaxis (26% recurrence rate).[82] Therefore, prophylaxis should be continued for 6 months in patients with fewer than three UTIs per year and for at least 12 months in adult patients with three or more UTIs per year.

Before chronic antimicrobial suppressive therapy is initiated, active infections must be completely eradicated with a full course of appropriate antibiotic therapy. The low doses of antimicrobials used for chronic prophylaxis suppress bacterial growth but do not eliminate active infection. Furthermore, surgically correctable anatomic abnormalities that predispose the patient to recurrent infections (e.g., obstruction, stones) should be ruled out.[34],[79],[80] Age also should be considered when contemplating chronic antimicrobial therapy. An asymptomatic, elderly patient taking many other medications is usually not an ideal candidate for chronic prophylactic treatment because of problems of non-adherence, cost, and potential drug interactions or toxicities.[79],[80] Younger patients, however, are good candidates for long-term suppressive therapy.[80]

Because T.W., a 28-year-old woman, has had at least three UTIs in the past few months, has undergone extensive evaluation, and has just been successfully treated with a standard course of trimethoprim, a 12-month course of antimicrobial prophylaxis would seem reasonable. She also should be evaluated at regular intervals for recurrent UTI and for the development of resistant organisms.

Although the foregoing discussion applies to antimicrobial prophylaxis in adults, the use of long-term prophylaxis of recurrent UTI in children remains controversial. One study examined risk factors for recurrent UTI and associations with antimicrobial prophylaxis in a prospective cohort study involving nearly 75,000 children 6 years of age or younger.[83] Among the children in this study, antimicrobial prophylaxis was not associated with decreased risk of recurrent UTI; however, prophylaxis was associated with a 7.5 times increased risk of infection caused by resistant bacteria. A second study examined 576 children younger than 18 years of age with a history of one or more microbiologically proven UTIs randomly assigned to receive either placebo or prophylaxis with TMP–SMX for 12 months.[84] Children randomly assigned to receive TMP–SMX experienced a 40% reduction in UTI during the study period; this benefit was independent of underlying risk factors such as history of vesicoureteral reflux. However, other outcomes such as hospitalization, secondary infections, or evidence of parenchymal disease on renal scans were not significantly different between groups; the one exception was that children receiving antibiotics were significantly more likely to experience UTI caused by an organism resistant to TMP–SMX.[84] Finally, a meta-analysis of 11 studies evaluating long-term antibiotic prophylaxis in children found no significant benefits of antibiotic administration overall.[85] Based on the conflicting data in the literature, current recommendations are that long-term antimicrobial prophylaxis should not be routinely recommended for prevention of recurrent UTI in children.[1–3,79,80,85–87]

CASE 71-6, QUESTION 8: What drugs could be appropriately used for long-term suppressive therapy in T.W?

Although numerous drugs are used for prophylaxis, TMP–SMX may be the drug of choice for chronic antimicrobial therapy owing to extensive experience, proven efficacy, infrequent toxicities, and low cost.[34],[80] TMP–SMX also has the effect of decreasing vaginal colonization with uropathogens.[34],[80] TMP–SMX single strength, either one-half or one full tablet daily, is commonly prescribed for chronic UTI prophylaxis and is an effective, well-tolerated, and convenient prophylactic regimen.[34],[80]

Successful prophylaxis, however, is significantly decreased in patients with urologic abnormalities or renal dysfunction. Also, infections that are not eradicated by a short-term therapeutic trial of TMP–SMX are not likely to respond to a long-term regimen.[79] Finally, enterococci may colonize introitally in patients taking chronic TMP–SMX.[82]

Fluoroquinolones are effective for chronic suppressive therapy but should be used only when antimicrobial resistance or intolerance to other recommended drugs is present. Cephalosporins also have been recommended, but they are best reserved for patients intolerant to or failing prophylaxis with other agents.[79],[80]

When selecting a drug for chronic antimicrobial therapy, it is important to consider efficacy, the likelihood that resistant organisms will develop, long-term toxicity, convenience, and cost to the patient. The most commonly used agents are listed in Table 71-5.

Based on the available information, T.W. could be switched to TMP–SMX. Although she has a history of GI distress because of this drug, this may not be a problem with the lower doses used for prophylaxis. If she is intolerant, trimethoprim alone, nitrofurantoin, or a fluoroquinolone also should be effective.

Cranberries and probiotics have long been of interest for their potentially beneficial effects in preventing UTI. Cranberries contain known compounds (i.e., flavonols, anthocyanidins, proanthocyanidin-tannins) that prevent E. coli from adhering to uroepithelial cells in the urinary tract.[88] A wide variety of cranberry products (e.g., juice concentrate, juice cocktail, cranberry extracts in capsules and tablets) and different dosing regimens have been evaluated in the prophylaxis of UTI, but the results are inconclusive overall and there are no formal recommendations regarding cranberry products for prevention of UTI.[88–90] A recent meta-analysis found that cranberry-containing products were effective in prevention of UTIs, with particular benefits seen in women (51% reduction in risk of infections), women with recurrent UTI (47% reduced risk of recurrences) and children (67% reduction in UTI risk).[88] However, this analysis also noted that available studies are quite heterogeneous, and the results of the meta-analysis should be interpreted with caution.[88] Probiotics (particularly Lactobacillus strains) may prevent colonization with pathogens associated with UTI.[91] Studies of probiotics for prophylaxis, however, are inconclusive at this time. Lack of standardization of ingredients (i.e. purity, dosage strengths) among available products and paucity of well-designed clinical studies are among the reasons for lack of clear recommendations regarding probiotics for this use. Further research is required to clarify unanswered questions regarding the role of cranberries or probiotics in the prevention of UTI.[88–91]

Urinary Tract Infection and Sexual Intercourse

CASE 71-7

QUESTION 1: On routine screening, asymptomatic bacteriuria is noted in W.W., a 30-year-old pregnant woman in her first trimester. Five years ago, during her first pregnancy, she experienced acute bacterial pyelonephritis, which required hospitalization and treatment with parenteral antibiotics. Since that time, she has had recurrent UTI, apparently related to sexual intercourse. These subsided when she began taking a single dose of nitrofurantoin after coitus, but she discontinued the practice before this pregnancy because she was afraid of the potential effects of this drug on the fetus. What is the association between sexual intercourse and the occurrence of UTI?

Table 71-5

Antimicrobial Agents Commonly Used for Chronic Prophylaxis Against Recurrent UTIs[1–3,5,77–79,82]

Agent	Adult Dose	Comments[a]
Nitrofurantoin	50–100 mg nightly	Contraindicated in infant <1 month of age. To be taken with food or milk. May cause brown or rust-yellow discoloration of urine.
Trimethoprim	100 mg nightly	Not recommended in children <12 years of age.
Trimethoprim 80 mg +	0.5–1 tablet nightly Or 3/week	Not recommended for use in infants

sulfamethoxazole 400 mg		<2 months. To be taken on an empty stomach with a full glass of water. Photosensitivity may occur.
Norfloxacin	200 mg/day	Avoid antacids; monitor theophylline levels.
Cephalexin	125–250 mg/day	
Cefaclor	250 mg/day	
Sulfamethoxazole	500 mg/day	

[a] Includes unique patient consultation information in italics.

Studies strongly support an association between sexual intercourse and UTI.[1–3,27] A direct relationship seems to exist between the number of days with intercourse within the previous week and the risk of developing a UTI.[1–3,27] One study found the relative risk of infection in women with 1, 4, and 7 days of intercourse within the previous week to be 1.4, 3.5, and 9.0, respectively, compared with women who were sexually inactive within the previous week. Another study found that the risk of UTI was doubled in women having intercourse more than 4 times/month compared with those women who did not.[27] Studies also indicate that introital colonization by fecal bacteria has a definite role in recurrent infections related to intercourse. The migration of these colonizing bacteria into the bladder appears to be facilitated during intercourse, but the exact mechanism remains unclear.[1–3] Because UTI are uncommon in men, transmission of an infection from the man is unlikely. Occasionally, bacteria harbored under the foreskin of an uncircumcised man may be transmitted to his partner through intercourse.[25]

CASE 71-7, QUESTION 2: Was it rational to treat W.W.'s repeated infections with a single dose of an antibiotic after intercourse?

Postcoital antibiotic prophylaxis is useful when recurrent UTI results from sexual intercourse. Theoretically, a single dose of an antimicrobial agent produces bactericidal activity in the urine before bacteria have a chance to multiply, and the infection is averted. Patients should be instructed to empty their bladder just after intercourse and before taking the medication to minimize the number of bacteria present in the bladder and to reduce dilution of the drug in the urine. Because most drugs effective for UTI are rapidly excreted by the kidney and quickly reach high urinary concentrations, this regimen is reasonable and decreases the incidence of postcoital infections.[92],[93] However, this practice is not recommended in patients with structural abnormalities of the urinary tract or decreased renal function. Symptomatic infection must be completely treated before beginning prophylaxis.

Depending on the frequency of intercourse, postcoital prophylaxis may result in less antibiotic use compared with continuous prophylaxis. TMP–SMX or nitrofurantoin is the most commonly recommended agent; however, other agents such as fluoroquinolones and cephalexin may be used.[77–93]

Urinary Tract Infection and Pregnancy

CASE 71-7, QUESTION 3: Because W.W. is asymptomatic at this time, should treatment be withheld because of her pregnancy?

W.W. should be treated because acute symptomatic lower UTI or pyelonephritis may develop in pregnant women with untreated bacteriuria. In addition, a UTI during pregnancy has been suggested to be associated with increased rates of preterm labor, premature delivery, and lower birth-weight infants.[27] A cause-and-effect relationship between UTI and maternal or infant risk has not been definitely established; in fact, a recent retrospective cohort study in nearly 86,000 mothers with or without UTI during pregnancy found no adverse pregnancy outcomes.[94] Nevertheless, treatment with an appropriate antimicrobial agent is currently recommended for all pregnant patients with significant bacteriuria.[13,28,29]

Nitrofurantoin is often recommended during pregnancy because teratogenic effects have not been observed clinically.[95,96] In vitro and retrospective investigations, however, suggest a slight mutagenic potential.[97,98] During lactation, nitrofurantoin could cause hemolytic anemia in a G6PD-deficient nursing infant; however, only small amounts have been detected in breast milk.[98] The fluoroquinolones are contraindicated in pregnancy because of the arthropathy observed in immature animals.[68]

The penicillins and cephalosporins are safe for use during pregnancy. These drugs, along with the others listed in Tables 71-3 and 71-5, cross the placental barrier; thus, the risk of toxicity or teratogenicity to the fetus must always be considered before deciding to treat a pregnant patient with a UTI.[98]

In this case, a cephalosporin or sulfisoxazole could be safely prescribed for treatment of W.W. Although sulfisoxazole is felt to be safe in the first trimester of pregnancy, trimethoprim and trimethoprim/sulfamethoxazole should be avoided because of the folate antagonist actions of trimethoprim and concerns regarding neural tube and cardiovascular defects potentially associated with maternal folate deficiency during the first trimester. Sulfisoxazole should not be used after 32 weeks of gestation because of concerns regarding neonatal hyperbilirubinemia, jaundice, and kernicterus. W.W. was correct in discontinuing her nitrofurantoin before pregnancy because of the risk to the fetus, although small, tends to offset the advantage of antimicrobial prophylaxis. W.W. must receive proper follow-up care.

CASE 71-7, QUESTION 4: For how long should W.W. be treated?

Few studies have compared single-dose and 3-day therapy with conventional 7-day therapy in pregnant patients. Available trials suggest, however, that cure rates of single-dose therapy were lower than 7- to 10-day therapy.[27],[95] Although more recent trials have shown that single-dose therapy effectively eradicates bacteriuria in pregnancy, these studies were conducted in a small number of patients. Therefore, similar to other populations, it is recommended that pregnant patients receive either a 3-day regimen or a 7- to 10-day regimen rather than single-dose therapy.[13],[27],[95]

Irrespective of the duration of therapy, appropriate follow-up of patients is crucial. Clinicians must document elimination of pathogens 1 to 2 weeks after therapy and follow the patient monthly for the remainder of gestation. If bacteriuria recurs, therapy should be given for relapse or reinfection and the patient evaluated radiologically for structural abnormalities.[1],[27]

ASYMPTOMATIC BACTERIURIA

Antibiotic Treatment

CASE 71-8

QUESTION 1: A.K., an asymptomatic 6-year-old girl, is found to have significant bacteriuria on routine screening. Should she be treated with an antimicrobial agent?

The treatment of patients with asymptomatic bacteriuria depends on the clinical setting in which it is found. Asymptomatic bacteriuria occurs in a heterogeneous group of patients with different prognoses and risks. Therefore, recommendations for treatment of asymptomatic patients with significant bacteriuria (two consecutive voided urine specimens showing $\geq 10^5$ bacteria/mL of urine in women, or a single clean-catch voided specimen in men) are based on specific age, sex, and clinical characteristics.[1],[10],[13],[28] These recommendations consider the risk for development of acute UTI and subsequent long-term complications. Generally, patients who benefit most from antibiotic treatment are those with urinary tract structural abnormalities, immunosuppressive therapy, and procedures requiring urinary tract instrumentation or manipulation.[1–3,13] Short-course regimens (i.e., single-dose or 3-day) are usually recommended when treatment is desired,[3] although longer regimens have also been recommended.[13]

Urinary tract infections in infants and preschool children (predominantly girls) occasionally are associated with renal tissue damage, although the incidence of renal damage has been estimated as low as 0.4% in children with previously normal renal function, and the overall risk of UTIs in this regard is now controversial.[9],[99] Asymptomatic bacteriuria of childhood is also important because it may be a manifestation of an anatomic or mechanical defect in the urinary tract. Therefore, it should be evaluated fully. Because most cases of renal scarring as a result of bacteriuria occur within the first 5 years of life, it is controversial whether treatment should be limited to infants and preschool children or whether all children should be treated regardless of age. Screening for bacteriuria in children and treating those with positive cultures, regardless of their clinical presentation, seems reasonable and is frequently recommended.[99] Treatment of A.K., although still controversial, seems prudent because any renal damage resulting from asymptomatic bacteriuria generally occurs during childhood. Should the decision be made to treat, principles of therapy are similar to those for symptomatic infections.

Pregnant Patients, the Elderly, and Other Adult Populations

CASE 71-8, QUESTION 2: The decision to treat the asymptomatic bacteriuria of A.K. was based primarily on the increased probability of renal damage during childhood. What other population groups should be treated for asymptomatic bacteriuria?

Without urinary tract obstruction, UTI in adults rarely lead to progressive renal damage.[3],[5] Therefore, asymptomatic bacteriuria does not require treatment in most adult patients who have no evidence of mechanical obstruction or renal insufficiency. As previously discussed, antimicrobial therapy is appropriate during pregnancy because as many as 40% of pregnant women with asymptomatic bacteriuria later develop symptomatic UTI, particularly pyelonephritis.[13] In addition, studies have confirmed associations between acute pyelonephritis during pregnancy with increased rates of preterm labor, premature delivery, and lower birth-weight infants.[27] The treatment of asymptomatic bacteriuria in pregnancy is therefore justified to decrease the risk of associated complications.[13]

Bacteriuria in the elderly is common; it is estimated that 20% of all women and 10% of all men aged 65 years and older have bacteriuria.[14],[15],[16] Although bacteriuria in this population often leads to symptomatic infection, clinical studies have consistently documented no beneficial outcomes in treated patients compared with untreated patients.[13],[15] Consequently, therapy is not recommended for the asymptomatic older patient because the expense, side effects, and potential complications of drug therapy appear to outweigh the benefits.[13],[15] Patients experiencing symptomatic infections should be treated as usual.

The treatment of asymptomatic bacteriuria in women with diabetes does not reduce complications and is not currently recommended.[13],[28]

SYMPTOMATIC ABACTERIURIA

Clinical Presentation

CASE 71-9

QUESTION 1: R.D., a 22-year-old woman, complains of urinary frequency and painful urination, which have developed during the past 4 to 5 days. UA reveals 10 to 15 WBC/LPF, but no bacteria are seen on a Gram stain of the urine. What is a reasonable assessment of R.D.'s clinical presentation?

Acute urethral syndrome is defined as symptoms consistent with lower UTI but with no organisms evident on Gram stain or culture. The lack of detectable pathogens may mean that the urine specimen is sterile or that the concentration of the organisms in the urine sample is low. Patients with these symptoms still may have a UTI even though the voided urine is sterile or contains less than 10^5 microorganisms/mL.[100] The causative organisms and the pathogenesis of infection in these cases are the same as for lower UTI. Other organisms that can cause urethritis in this setting, especially in the presence of pyuria, are Chlamydia trachomatis, Neisseria gonorrhoeae, and Trichomonas vaginalis.[100] Conversely, in patients with acute urethral syndrome without pyuria, noninfectious causes of urethritis are common and should be sought. Because R.D. is symptomatic, has 10 to 15 WBC/LPF in her urine, and no bacteria on Gram stain, infection with C. trachomatis or some other more atypical pathogen is likely.

Interstitial cystitis, also known as painful bladder syndrome or bladder pain syndrome, is a chronic clinical syndrome characterized by bladder or pelvic pain and urinary frequency or urgency.[101] Although the exact cause of interstitial cystitis is not known, it is apparently not an infection-related disorder and does not respond to antibiotic therapy. The clinical presentation of interstitial cystitis is very similar to that of symptomatic abacteriuria, but absence of pyuria is a key difference. Interstitial cystitis should be suspected in patients with clinical findings suggestive of lower UTI but who do not manifest pyuria and who have not responded to previous empiric antibiotic therapy; no antibiotics should be administered without further diagnostic evaluation.[101]

Antibiotic Treatment

CASE 71-9, QUESTION 2: Should R.D. be treated with antibiotics?

A double-blind, placebo-controlled study evaluated the use of doxycycline 100 mg twice a day (BID) in patients with UTI and low bacterial counts. Clinical cure of bacteriuria and pyuria was significantly greater in the doxycycline-treated group, but doxycycline did not reduce symptoms in patients without pyuria.[100] Because E. coli, other gram-negative bacteria, and C. trachomatis are the usual causes of acute urethral syndrome, an antibiotic such as doxycycline with activity against Chlamydia is a reasonable initial treatment for patients such as R.D. presenting with urinary tract symptoms (without bacteriuria) and with pyuria. All tetracyclines and sulfonamides, with or without trimethoprim, also are likely to be effective in such patients, but doxycycline has been best studied to date. Of the fluoroquinolones, newer agents, such as levofloxacin, offer promise as alternatives to doxycycline but have not been well studied in this setting.[100] Azithromycin as a single dose also has a major role in treating chlamydial infections (see Chapter 72, Sexually Transmitted Diseases).

Prolonged therapy of 2 to 4 weeks in duration and treatment of sexual partners may be required to prevent reinfection through intercourse. Prolonged therapy is appropriate if the patient has a history consistent with Chlamydia urethritis; a sexual partner with recent urethritis; a recent new sexual partner; a gradual, rather than abrupt, onset of symptoms that has occurred during a period of days (as in R.D.); and no hematuria. Patients without such a history can be treated with a short course of antibiotics as any other patient with a lower UTI.

HOSPITAL-ACQUIRED ACUTE URINARY TRACT INFECTION

CASE 71-10

QUESTION 1: P.M., an alert, 70-year-old woman with chest pain, was hospitalized to rule out acute myocardial infarction. This is her third hospitalization for chest pain in the past 6 months. A urinary catheter was temporarily placed as part of her routine medical care. Two days after admission, she complained of burning on urination and bladder pain. TMP–SMX double-strength, one tablet BID was ordered after microscopic examination of the urine indicated a UTI. Was this empiric therapy appropriate?

Hospital-acquired (or nosocomial) UTIs occur in about one-half million patients per year and most are associated with the use of indwelling bladder catheters. Approximately 10% to 30% of catheterized patients exhibit infection.[23] Complications of catheter-associated UTI are significant. Nosocomial UTIs are the source of up to 15% of all nosocomial bloodstream infections, occurring in about 4% of all catheterized patients[23]; the associated mortality rate is approximately 15%.[23] Nosocomial UTI also prolongs hospitalization by an average of 2.5 days and costs an additional $600 to $700.[23] Prevention is the best way to manage nosocomial UTI, but antibiotic treatment is usually initiated in hospitalized patients who exhibit UTI symptoms.

The susceptibility of hospital-acquired pathogens to antimicrobial agents differs from community-acquired bacteria, and these susceptibilities frequently vary from one hospital to another. Therefore, the microbiology department of a particular hospital should be consulted to determine current trends in the antibiotic susceptibility of bacteria acquired in that setting. In general, E. coli is still the predominant urinary tract pathogen. An increased proportion of infections is caused, however, by other gram-negative bacteria such as Proteus and Pseudomonas, gram-positive pathogens such as Staphylococcus and Enterococcus, and yeast (e.g., Candida).[21],[23]

Repeated courses of antibiotic therapy, anatomic defects of the urinary tract, old age, increased length of hospital stay, and repeated hospital admissions are associated with a higher incidence of infection with antibiotic-resistant organisms.[21],[23],[102] Pseudomonas, Proteus, Providencia, Morganella, Klebsiella, Enterobacter, Citrobacter, and Serratia are particularly difficult to eradicate because they usually are less susceptible to commonly used antimicrobial agents.

P.M. is elderly, hospitalized, and has been repeatedly exposed to potentially resistant organisms during her previous hospitalizations. Oral fluoroquinolones are most commonly used as empiric therapy in this setting because of their greater activity against potentially resistant pathogens compared to TMP–SMX; however, TMP–SMX is an acceptable empirical therapy in P.M. as long as her clinical and laboratory data are appropriately monitored.[21],[23],[103] Cultures of P.M.'s urine should be performed and, once C&S test results are known, therapy promptly changed according to susceptibility reports. To achieve the most cost-effective therapy, oral agents should be administered to all patients capable of taking medications by mouth unless the isolated pathogens are resistant to oral medications, or underlying GI dysfunction makes adequate absorption of oral antibiotics questionable.[23],[75],[103] The recommended duration of antibiotic therapy for patients such as P.M., who present with mild-to-moderate symptoms, is 5 to 7 days; patients who do not respond promptly to treatment may be treated for a total of 10 to 14 days.[23]

CASE 71-10, QUESTION 2: If P.M. had additional symptoms of fever, chills, flank pain, and vomiting, how would her treatment differ?

In seriously ill patients with possible sepsis, broad-spectrum parenteral antibiotics with activity against P. aeruginosa are usually preferred as initial therapy (Table 71-4). Suitable antibiotic choices include antipseudomonal cephalosporins (e.g., ceftazidime, cefepime), extended-spectrum penicillins (e.g., piperacillin-tazobactam), carbapenems (imipenem-cilastatin, meropenem), IV fluoroquinolones (e.g., ciprofloxacin, levofloxacin), and aztreonam. These antibiotics are at least as effective as the aminoglycosides and lack the ototoxic and nephrotoxic potential. However, these fluoroquinolone and β-lactam agents are more costly and associated with the emergence of resistant organisms and superinfection.

In general, antipseudomonal β-lactam antibiotics remain the drugs of choice for nosocomial urologic sepsis.[103] Although combination therapy may be useful initially in neutropenic patients with urologic sepsis, it should be narrowed to single-agent therapy once culture results are available.[103] The recommended duration of antibiotic therapy in seriously ill patients is 10 to 14 days.[23]

Urinary Catheters

CASE 71-11

QUESTION 1: J.W., an 18-year-old woman, was hospitalized after a diving accident that resulted in a spinal cord injury with paralysis. Included among several initial interventions was insertion of an indwelling catheter with a closed drainage system because of bladder incontinence. Two weeks after admission to the hospital, J.W. has developed asymptomatic bacteriuria. Should this be treated?

A systemic antibiotic selected specifically for the infecting organism will temporarily result in sterile urine. Reinfection, often by a resistant organism, occurs in 30% to 50% of these cases if closed drainage catheterization is continued during therapy.[1,23] For this reason, it generally is recommended that systemic antimicrobial therapy be initiated after or just before catheter removal.[1,23,104] Because long-term catheterization is necessary in many patients and because bacteriuria is an inevitable consequence, it is often recommended that asymptomatic patients (such as J.W.) be left untreated to avoid the complications of recolonization and potential infection with resistant organisms.[1,13,23,104] Therapy must be started, however, if fever, flank pain, or other symptoms indicative of an actual UTI develop.[1,23]

CASE 71-11, QUESTION 2: Is systemic antimicrobial prophylaxis useful for J.W.?

The benefits of systemic antibiotics in preventing catheter-induced UTI are not clear. Studies using closed drainage systems with diligent catheter care indicate that systemic antibiotics decrease the daily and overall incidence of infection in patients with sterile urines before catheterization.[35,36] The preventive effect of antimicrobials is greatest for short-term catheterizations or during the first 4 to 7 days of long-term catheterization.[35,36] Thereafter, the rate of infection increases. Although the overall infection rate remains lower than in untreated patients, the emergence of resistant organisms is significant. Therefore, in deciding to use systemic antimicrobials, it is important to consider the patient's underlying diseases, risk factors, probable duration of catheterization, and potential complications of drug toxicity or resistant organisms that can result from the chronic use of antimicrobials. Because long-term catheterization is anticipated for J.W., antimicrobial prophylaxis for J.W. is not recommended.[23]

CASE 71-11, QUESTION 3: J.W. eventually recovers urinary continence and the catheter is able to be removed. However, 2 days after removal of the catheter, she still has asymptomatic bacteriuria. How should she be managed?

Because asymptomatic bacteriuria in patients with urinary catheters is very common (approximately 25% with short-term catheterization and virtually 100% long-term) but is associated with few complications, antibiotic therapy for asymptomatic bacteriuria is not recommended as long as the catheter remains in place.[23] However, antibiotic treatment may be considered in asymptomatic women with catheter-acquired bacteriuria that persists >48 hours after catheter removal.[13],[23] Such patients may be treated with either a single large dose or a 3-day regimen of TMP–SMX, even if the patient is asymptomatic.[13],[23],[24] Older women (>65 years) probably should be treated with a 10-day course; however, the optimal duration in this age group is unknown. Whether these same treatment regimens are advisable in male patients requires further study.[23]

PROSTATITIS

Incidence, Prevalence, and Epidemiology

Prostatitis is an acute or chronic inflammatory condition affecting the prostate, approximately 5% of cases being caused by proven bacterial infections.[11],[12] Other noninfectious types of prostatitis include chronic calculus prostatitis, nonbacterial prostatitis, and prostatodynia.[11],[12] Chronic bacterial prostatitis, defined as prostatitis in which symptoms persist for at least 3 months, is one of the most common causes of recurrent UTI in men. The lifetime probability of a man being diagnosed with prostatitis is greater than 25%; recurrence rates reportedly range from 20% to 50%.[11],[12] Approximately 5% of men with acute prostatitis will experience chronic infection.[11]

Etiology, Pathogenesis, and Predisposing Factors

ACUTE BACTERIAL PROSTATITIS

Acute bacterial prostatitis in most patients probably begins as an ascending infection of the urethra. A simple UTI then eventually involves reflux of infected urine into the ejaculatory and prostatic ducts through the prostate gland, where bacteria are difficult to eradicate.[12] Acute prostatitis may also result from urethral stricture or after instrumentation of the urinary tract or prostate biopsy, especially in the presence of bacteriuria at the time of the procedure.[12] Bacterial prostatitis is predominantly caused by aerobic gram-negative bacilli, with E. coli causing 50% to 90% of cases. Other Enterobacteriaceae such as Proteus and Klebsiella account for an additional 10% to 30% of cases, followed by Enterococcus (5% to 10%) and Pseudomonas

(<5%); less common causes include staphylococci, streptococci, and atypical organisms such as C. trachomatis, T. vaginalis, and Ureaplasma urealyticum.[11],[12]

CHRONIC BACTERIAL PROSTATITIS

Chronic prostatitis is commonly associated with spinal cord injuries, infectious stones, anatomic or physiologic abnormalities of the urinary tract such as obstruction or voiding dysfunction, and immune dysfunction. However, recurrent infections are also commonly caused by relapses of acute prostatitis caused by persistence of bacteria in the prostate.[11],[12] Normally, men secrete a prostatic antibacterial factor; however, this substance is often absent or significantly reduced in men with chronic prostatitis. The most common pathogens isolated from chronic bacterial prostatitis are E. coli (>80% of cases) and other gram-negative bacilli, although atypical bacteria have also been more commonly reported in chronic prostatitis compared to acute infections.[11],[12]

Clinical Presentation and Diagnosis

ACUTE BACTERIAL PROSTATITIS

Acute bacterial prostatitis is characterized by the sudden onset of chills and fever; perineal and low back pain; urinary urgency and frequency; nocturia, dysuria, and generalized malaise; and prostration. Patients may also complain of myalgias, arthralgias, and symptoms of bladder outlet obstruction. Rectal examination usually discloses an exquisitely tender, swollen prostate that is firm and warm to the touch. The pathogens generally can be identified by culture of the voided urine. In patients with acute bacterial prostatitis, prostatic massage (see following discussion) should be avoided because of patient discomfort and the risk of bacteremia.[11],[12] The diagnosis of acute prostatitis is therefore usually based on clinical presentation and physical examination.

CHRONIC BACTERIAL PROSTATITIS

The clinical manifestations of chronic bacterial prostatitis are highly variable and many patients are asymptomatic. The disease usually is suspected when a male patient treated for UTI or acute prostatitis relapses. The diagnosis of chronic prostatitis is confirmed by examination of expressed prostatic secretions.[11],[12] To ensure accurate localization (i.e., to distinguish prostatic from urethral bacteria), segmented urine samples are taken. The first 10 mL of voided urine represents the urethral sample, the midstream urine collected represents the bladder sample, and the first 10 mL voided immediately after prostatic massage represents the prostate sample. When the bladder sample is sterile or nearly so, bacterial prostatitis is diagnosed if the bacterial count in the prostate sample is at least one logarithm greater than that in the urethral sample.[11],[12]

Overview of Treatment

Treatment of bacterial prostatitis is challenged by poor penetration of many antibiotics across the non-fenestrated prostatic capillaries and through prostatic epithelium into infected tissues and fluids. Fluoroquinolones are often considered the preferred antibiotics for treatment of acute or chronic prostatitis because of good penetration into the prostate (10%–50% of serum concentrations) and good activity against most causative pathogens, although fluoroquinolone resistance has become a growing problem.[11],[12] Trimethoprim alone or TMP–SMX are also commonly used agents. β-Lactams, tetracyclines, macrolides, and clindamycin have also been successfully used in the treatment of both acute and chronic infections, but their penetration into the prostatic tissues and fluids may be somewhat less than the fluoroquinolones or TMP–SMX. Also, the antimicrobial activity of these drugs is not necessarily ideal for covering the most common causative pathogens.[11],[12] The duration of antibiotic therapy in acute prostatitis is usually 2 to 4 weeks, depending on the severity of the infection and rate of response to treatment.[11],[12] Chronic prostatitis is usually treated for 4 to 6 weeks, although longer courses may be required in the presence of prostate stones or other types of genitourinary pathology, and long-term suppressive therapy is sometimes used for patients with a history of rapid and/or multiple recurrences.[11],[12] Monitoring parameters consist primarily of clinical signs and symptoms, and the end point of treatment is complete resolution of clinical findings.[11],[12] Supportive treatment consists primarily of drugs for symptomatic relief such as acetaminophen or nonsteroidal anti-inflammatory agents; warm compresses to the perineal area are also sometimes recommended, although there are few data to support this practice.[11],[12]

CASE 71-12

QUESTION 1: D.G., a 60-year-old man, experienced his first UTI at age 40, with symptoms of frequency, dysuria, nocturia, perineal pain, fever and chills but no flank pain. Acute prostatitis was diagnosed. E. coli was cultured from the urine, and treatment with a sulfonamide was successful. After 12 asymptomatic years, acute prostatitis caused by E. coli recurred and again responded to sulfonamide therapy. Two more E. coli infections that responded to sulfonamide therapy occurred during the next 8 years. Why were sulfonamides appropriate treatment for D.G.'s repeated acute episodes of bacterial prostatitis?

Most antibacterial drugs appropriate for UTI, including sulfonamides, can be used to treat acute bacterial prostatitis because the diffuse, intense inflammation of the prostate gland allows many drugs to readily penetrate into the prostatic fluid and tissues. Antimicrobial therapy should be continued for at least 2 to 4 weeks to prevent the development of chronic prostatitis.[11],[12],[24]

CASE 71-12, QUESTION 2: Taking into account the pathophysiology of prostatitis, what would be a reasonable choice of therapy for D.G. should he have future recurrences of prostatitis?

In addition to antibiotics, other supportive measures may provide symptomatic relief to patients with acute bacterial prostatitis. These measures include liberal hydration, nonsteroidal anti-inflammatory drugs for pain relief, sitz baths, and stool softeners.

In retrospect, sulfonamides were appropriate for D.G. because they effectively treated his infections. Other options, particularly the fluoroquinolones, would also have been appropriate in the treatment of D.G.'s episodes of acute prostatitis.

Most antibiotics that are acidic do not readily cross the prostatic epithelium into the alkaline prostatic fluid except in the presence of acute inflammation. Theoretically, the high alkalinity of prostatic fluids should impair the diffusion of trimethoprim and enhance the diffusion of tetracyclines, certain sulfonamides, and macrolide antibiotics, such as erythromycin. Nevertheless, TMP–SMX historically has the best documented cure rates in the treatment of acute and chronic bacterial prostatitis. Long-term therapy of chronic bacterial prostatitis with TMP–SMX for 4 to 16 weeks is associated with a cure rate of 32% to 71%, which significantly exceeds the cure rate associated with short-term therapy of 2 or fewer weeks.[11],[12]

The fluoroquinolones are alternatives to TMP–SMX and are now considered by many to be the agents of choice for the treatment of prostatitis.[11],[12],[24] A number of studies have documented bacteriologic cure in 80% to 90% of patients treated with norfloxacin, ciprofloxacin, or levofloxacin for 4 to 12 weeks, rates comparable to or substantially higher than those achieved with TMP–SMX.[11],[12] The fluoroquinolones have an important role in the treatment of prostatitis owing to their bactericidal activity against common pathogens and excellent penetration into prostatic tissues and fluid. The fluoroquinolones are often used as initial empiric therapy of prostatitis and are also excellent alternatives to other agents in patients who are unresponsive or intolerant to conventional therapy, or in those infected with resistant organisms.[11],[12],[24] Fluoroquinolones also have been used for chronic suppressive therapy (one-half normal doses) in patients who relapse after conventional treatment.[1]

D.G. should be treated with TMP–SMX for a minimum of 6 weeks; some authorities recommend a 2- to 3-month total course of therapy. If an adequate trial of TMP–SMX is unsuccessful, fluoroquinolone therapy can be used. Alternatively, a fluoroquinolone could be used as initial therapy for this or future episodes.[11],[12],[24]

If D.G. continues to experience recurrent infections after a trial of fluoroquinolone therapy, chronic low-dose treatment with TMP–SMX, fluoroquinolones, or nitrofurantoin can alleviate the symptoms of episodic bladder infection associated with chronic bacterial prostatitis. Infections eventually recur with greater frequency in most of these patients. Chronic, low-dose antibacterial therapy sterilizes the bladder, alleviates symptoms, confines bacteria to the prostate, and prevents infection of and damage to the rest of the urinary tract. Chronic bacterial prostatitis is one of the few indications for continuous antibiotic therapy.

Sexually Transmitted Diseases

Jeffery A. Goad, Karl M. Hess, and Albert T. Bach

CORE PRINCIPLES

		CHAPTER CASES
	GROWTH AND DEVELOPMENT	
1	Urethral gonorrhea is initially characterized in males by a purulent discharge associated with dysuria. Discharge may become more profuse and blood tinged as the infection progresses. Some strains of gonorrhea have a propensity to cause asymptomatic or minimally symptomatic infections.	**Case 72-1 (Question 2)**
2	In females, the most common symptom of urethral gonorrhea is vaginal discharge. Many women infected with gonorrhea have abnormalities of the cervix, including purulent or mucopurulent endocervical discharge, erythema, friability, and edema of the zone of ectopy. Pelvic inflammatory disease (PID) is a serious complication and can lead to infertility and chronic pelvic pain.	**Case 72-1 (Question 4)**
3	The standard of treatment for gonorrhea is third-generation cephalosporins, such as ceftriaxone. Fluoroquinolones should not be used owing to high levels of resistance.	**Case 72-1 (Questions 6, 7)**
4	Depending on the site of exposure, gonococcal infections may also cause anorectal and pharyngeal infections. Anorectal infections may cause proctitis with anorectal pain, mucopurulent anorectal discharge, constipation, tenesmus, and anorectal bleeding. Pharyngeal infections may be characterized by sore throat, pharyngeal exudates, or cervical lymphadenitis. The treatment for anorectal or pharyngeal gonorrhea is ceftriaxone.	**Case 72-2 (Questions 2–4)**
5	Disseminated gonococcal infection (DGI) can lead to complicated gonorrhea infections that cause pustular acral skin lesions, tenosynovitis, polyarthralgia, or arthritis. DGI may also lead to rare cases of perihepatitis, endocarditis, or meningitis. Treatment for DGIs requires high-dose ceftriaxone.	**Case 72-4 (Questions 2, 3)**
	PELVIC INFLAMMATORY DISEASE	
1	PID may be treated on an inpatient or outpatient basis. Those with mild-to-moderate PID can be admitted and treated with parenteral antibiotics; however, clinical efficacy and overall outcomes are equal between parental and oral therapy.	**Case 72-3 (Question 1)**

NONGONOCOCCAL URETHRITIS

1	Nongonococcal urethritis (NGU) is a common sexually transmitted disease (STD) in males and is frequently caused by Chlamydia trachomatis.	**Case 72-5 (Question 1)**
2	NGU typically produces less severe and less frequent dysuria and less penile discharge as compared with gonococcal urethritis. NGU and gonococcal urethritis cannot be reliably differentiated on the basis of symptoms and signs.	**Case 72-5 (Question 2)**
3	NGU may be treated with either azithromycin or doxycycline; however, azithromycin is superior in its coverage of both Mycoplasma genitalium and Chlamydia.	**Case 72-5 (Questions 3, 4)**

LYMPHOGRANULOMA VENEREUM

1	Lymphogranuloma venereum (LGV) is characterized by three stages of infection and may be treated with either doxycycline, erythromycin base, or azithromycin.	**Case 72-6 (Questions 1, 2)**

SYPHILIS

1	Syphilis is characterized by four stages of infection: primary, secondary, latent, and tertiary. Penicillin G is the drug of choice for all stages of syphilis.	**Case 72-7 (Questions 1, 3, 4), Case 72-8 (Question 1)**
2	The Jarisch–Herxheimer reaction is a benign, self-limited complication of antibiotic therapy that may develop after treatment of primary and secondary syphilis.	**Case 72-8 (Question 2)**

CHANCROID

1	Uncircumcised males have an increased risk of infection and may not respond to therapy as well as circumcised males. Current treatment options include azithromycin, ceftriaxone, ciprofloxacin, and erythromycin base.	**Case 72-9 (Questions 1, 2)**

VAGINITIS

1	Common causes of vaginitis include bacterial vaginosis, trichomoniasis, and vulvovaginal candidiasis. General symptoms may include itching, burning, irritation, and abnormal discharge and can be differentiated based on signs, symptoms, and laboratory testing.	**Case 72-10 (Question 1), Case 72-11 (Questions 2–4), Case 72-12 (Question 1)**
2	Vulvovaginal candidiasis may be effectively treated with nonprescription medications; however, patients must be assessed fully before self-treatment is initiated.	**Case 72-11 (Questions 1, 6–9)**

GENITAL HERPES

①	Genital herpes, transmitted either from symptomatic or asymptomatic individuals, often presents with painful vesicles in those with HSV-2 primary infection, and recurrent infections are common, although the frequency decreases with time.	**Case 72-14 (Questions 1–3)**
②	Genital herpes is best treated with oral antivirals, such as acyclovir or valacyclovir, and prevented with either suppressive or standby antivirals.	**Case 72-14 (Question 5)**

GENITAL WARTS

①	Genital HPV warts are highly contagious and may now be prevented by vaccination, in addition to condoms.	**Case 72-17 (Question 1)**
②	Genital warts often recur even with treatment, which is primarily local, including antimitotics, immune modulators, chemical and surgical ablation, and cryotherapy.	**Case 72-17 (Question 1)**

Sexually transmitted diseases (STDs) are discussed in the earliest written records. However, only in the last several decades have the common STDs been differentiated from each other; unique STD syndromes continue to be described today. For example, of the common STDs, bacterial vaginosis (BV) was not described clearly as a syndrome (initially called Haemophilus vaginalis vaginitis) until the 1950s; herpes simplex virus (HSV) type 2 (the cause of genital herpes) was not differentiated from HSV type 1 until the 1960s; the spectrum of genital chlamydial infections was not defined until the 1970s; and the human immunodeficiency virus (HIV) as an STD was not recognized until the 1980s. Since 1980, eight additional sexually transmitted pathogens have been identified. They include the human papillomaviruses (HPV), human T-lymphotropic virus (HTLV-I and II), Mycoplasma genitalium, Mobiluncus species, HIV-1 and -2, and the human herpes virus type 8 (associated with Kaposi sarcoma).[1] More recently, the Centers for Disease Control and Prevention (CDC) report while hepatitis C virus (HCV) infection is not efficiently transmitted through sexual contact, men who have sex with men (MSM) coinfected with HIV are more likely to transmit to HCV than through heterosexual contact.[2] See http://www.cdc.gov/std/training/othertraining.htm for general resources from the Centers for Disease Control and Prevention for various sexually transmitted diseases.

GONORRHEA

Gonorrhea (see http://www.cdc.gov/std/training/clinicalslides/slides-dl.htm for symptoms of this STD) is caused by Neisseria gonorrhoeae, a gram-negative diplococcus. Depending on the site of exposure, this disease can cause uncomplicated cervical, urethral, rectal, and oropharyngeal infections in both males and females. N. gonorrhoeae infection in women is also a major cause of pelvic inflammatory disease (PID). Disseminated gonococcal infection (DGI), the bactermic spread of N. gonorrhoeae to joints and other tissues, can lead to complicated gonorrhea infections that cause pustular acral skin lesions, tenosynovitis, polyarthralgia, or arthritis. DGI may lead to rare cases of perihepatitis, endocarditis, or meningitis. In the 1930s, sulfonamides became the first form of effective antimicrobial therapy for gonorrhea until penicillins and tetracyclines became the mainstays of therapy; however, the high levels of resistance to these two antimicrobial agents have eliminated their use in the treatment of this disease state.

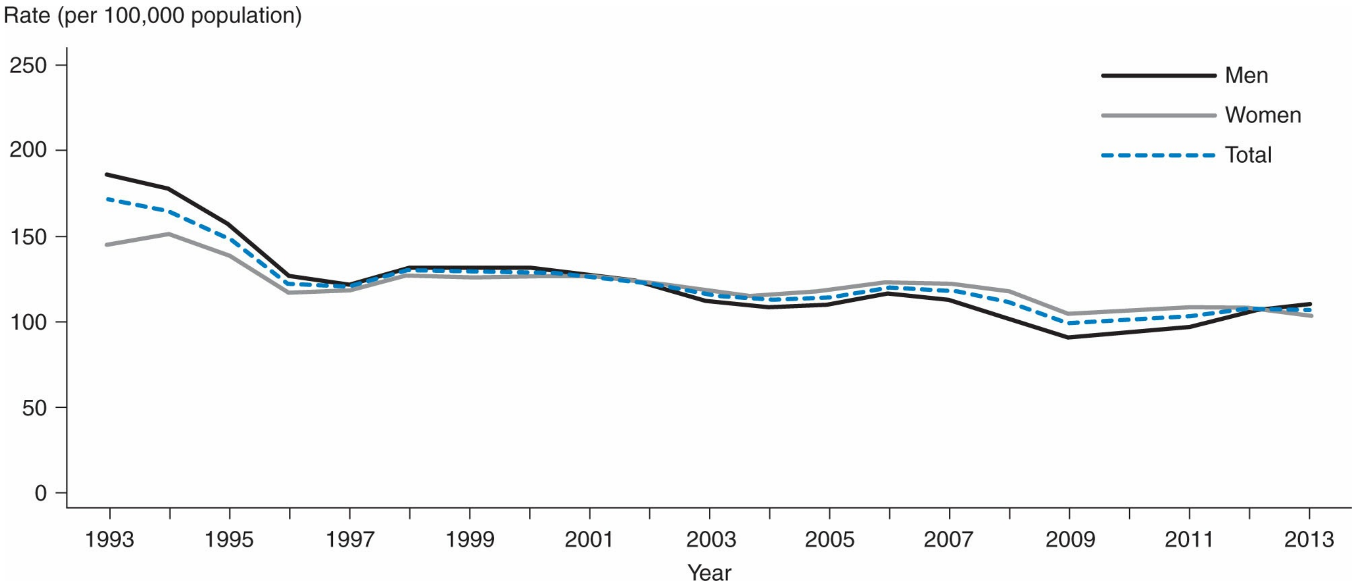

Figure 72-1 Gonorrhea: rates by sex, United States, 1993 to 2013. Note: the Healthy People 2020 target for gonorrhea is 257 new cases per 100,000 for females aged 15 to 44 and 198 new cases per 100,000 for males aged 15 to 44. Source: Centers for Disease Control and Prevention. Sexually Transmitted Disease Surveillance 2013. Atlanta, GA: US Dept of Health and Human Services; 2014.

In the United States, the incidence of gonorrhea fell 74.3% between 1975 and 1997 after the establishment of national gonorrhea control programs. From 1996 to 2006, the rate fluctuated at around 115 cases per 100,000 individuals, and from 2006 to 2009, the rates declined to a historic low of 98.1 cases per 100,000 individuals in 2009.[3],[4] After slight rate increases each year from 2009, the national gonorrhea rate of 106.1 cases per 100,000 individuals in 2013 (representing a total of 333,004 cases) was a decrease from 107.5 in 2012.[4] The current Healthy People 2020 goals for gonorrhea are 257 cases per 100,000 women aged 15 to 44 and 198 cases per 100,000 men aged 15 to 44 (Fig. 72-1).[5] Although there was a decrease of 9.1% in gonorrhea rates among African Americans from 2009 to 2013, rates of gonorrhea remain the highest among African Americans compared to other race and ethnic groups. During this same time period, all other race and ethnic groups saw an increase in gonorrhea rates.[4]

The highest incidence of gonorrhea is in men aged 20 to 24 years and in women aged 15 to 24 years of age. Additional risk factors for women acquiring gonorrhea include a previous gonococcal or other STD infection, new or multiple sex partners, inconsistent condom use, or engaging in commercial sex work or drug use.[6] Although the risk of gonorrhea was greater in homosexual men than in heterosexual men in the past, the incidence dropped in homosexual men during the 1980s AIDS epidemic, because of a reduction in sexual risk behaviors. Currently, the incidence of gonorrhea in MSM continues to rise, from 21.5% in 2006 to 35.1% in 2013.[4]

Uncomplicated Gonorrhea

TRANSMISSION

CASE 72-1

QUESTION 1: D.S., a 23-year-old male naval officer recently stationed in the Philippines, complains of dysuria, meatal pain, and a profuse yellow urethral discharge for 2 days. He admits to extramarital sex with a prostitute during the past week. He is accompanied by his pregnant wife, C.S., who is asymptomatic. D.S. engages in vaginal sex but there is no history of oral or anal sex with either partner. Assuming the prostitute has gonorrhea, what is the likelihood that D.S. and C.S. have been infected?

After one or two episodes of unprotected vaginal intercourse with an asymptomatic infected prostitute, a man has approximately 50% risk of acquiring a urethral infection; the risk increases with repeated exposures and high prevalence among commercial sex workers.[7] The prevalence of infection in women who are secondary sex contacts of infected men is as high as 80% to 90%.[8] Therefore, the likelihood that D.S. and C.S. are infected is high. Because D.S. had sex with a prostitute, both D.S. and C.S. should also be tested for HIV infection.

SIGNS AND SYMPTOMS: MALES

CASE 72-1, QUESTION 2: What signs and symptoms in D.S. are consistent with the diagnosis of gonorrhea? Describe D.S.'s anticipated clinical course if he remains untreated.

In men, gonorrhea usually becomes clinically apparent 1 to 7 days after contact with an infected source. A purulent discharge associated with dysuria is the first sign of infection; D.S. exhibits both. The discharge, which is presumably caused by chemotactic factors such as C5a released when antigonococcal antibody binds complement, may become more profuse and blood tinged as the infection progresses. Some strains of gonorrhea have a propensity to cause asymptomatic or minimally symptomatic infection with negative Gram stain.

Patients with asymptomatic or minimally symptomatic disease may serve as reservoirs for the infection, evading treatment for prolonged periods.[9] At one time, only women were thought to have asymptomatic gonorrhea, but now it is known that men may be asymptomatic carriers as well.[10]

In the area before antimicrobials, gonococci occasionally spread to the epididymis, causing unilateral epididymitis; the prevalence was 5% or more in patients in some studies. Now epididymitis occurs in less than 1% of men with gonorrhea. Urethral stricture after repeated attacks and sterility after epididymitis are rare complications of gonococcal infection owing to the effectiveness of antibiotics.

Table 72-1

CDC Recommendations for Treatment of Uncomplicated Gonorrhea

Presentation	Drugs of Choice (% Cured)	Dosage	Alternative Regimens
Urethritis, cervicitis, rectal[a]	Ceftriaxone (99.2)	250 mg IM once	Cephalosporin single dose regimens[b]
Pharyngeal[a]	Ceftriaxone (98.9)	250 mg IM once	

[a] Because a high percentage of patients with gonorrhea have coexisting Chlamydia trachomatis infections, many clinicians recommend treating all patients with gonorrhea with a single-dose azithromycin 1 g orally for treatment of Chlamydia.

[b] Additional cephalosporin regimens include cefixime 400 mg PO, ceftizoxime 500 mg IM, cefoxitin 2 g IM (administered with probenecid 1 g PO), and cefotaxime 500 mg IM.

Adapted from Workowski KA, Bolan GA; Centers for Disease Control and Prevention (CDC). Sexually transmitted diseases treatment guidelines, 2015. MMWR Recomm Rep. 2015;64(RR-03):1–137.

DIAGNOSIS: MALES

CASE 72-1, QUESTION 3: Intracellular gram-negative diplococci were seen on the Gram stain of D.S.’s urethral exudate. Is any further diagnostic testing required?

Demonstration of intracellular gram-negative diplococci in the gram-stained exudate confirms the diagnosis in symptomatic men. Until recently, some experts recommended that cultures be reserved for individuals with negative Gram stain of urethral exudate. However, today cultures are recommended for all patients to permit isolation and testing of the bacteria for antibiotic susceptibility. Cultures usually are performed on Thayer–Martin medium, an enriched chocolate agar to which vancomycin, colistimethate, and nystatin have been added. Cultures from the throat should be obtained if D.S. were exposed by cunnilingus to the prostitute. In D.S.’s case, a urethral culture is indicated.

SIGNS AND SYMPTOMS: FEMALES

CASE 72-1, QUESTION 4: C.S., D.S.’s wife, is asymptomatic. What symptoms would be consistent with gonorrhea in C.S.? Do the symptoms differ because she is pregnant? What is the natural course of gonorrhea in women if left untreated?

Urogenital gonococcal infections in women are commonly asymptomatic. Because the endocervical canal is the primary site of urogenital gonococcal infection in women, the most common symptom is vaginal discharge. Many women infected with gonorrhea have abnormalities of the cervix, including purulent or mucopurulent endocervical discharge, erythema, friability, and edema of the zone of ectopy.[8] The incubation period for urogenital gonorrhea in women is variable.[11] PID is a serious complication in 10% to 20% of women with acute gonococcal infection and can lead to infertility and chronic pelvic pain.[8],[12] The assessment of signs and symptoms in women with gonorrhea often is confounded by nonspecific signs and symptoms and a high prevalence of coexisting infection, especially with Chlamydia trachomatis or Trichomonas vaginalis.

Although lower genital tract symptoms in women may disappear, they remain carriers of N. gonorrhoeae and should be treated. Complications of urogenital gonorrhea in pregnancy include spontaneous abortion, premature rupture of the fetal membranes, premature delivery, and acute chorioamnionitis.[12–14] Other complications include gonococcal arthritis (see Case 72-4, Question 1) conjunctivitis, and ophthalmia neonatorum in the newborn.[15] For these reasons, it is critical that C.S. be worked up thoroughly for gonorrhea.

DIAGNOSIS: FEMALES

CASE 72-1, QUESTION 5: How should gonorrhea be ruled out in C.S.?

Nucleic acid amplification tests (NAATs), such as polymerase chain reaction, are recommended for the detection of N. gonorrhoeae at urogenital sites in men and women regardless if symptoms are present.[16] Although NAATs are not FDA approved for the detection of N. gonorrhoeae at non-urogenital sites, laboratories should meet CLIA requirements and performance specifications for use with rectal and oropharyngeal specimens; NAATs are the recommended detection method for rectal and orophyarynageal specimens. Although culture for N. gonorrhoeae is not ideal for routine diagnosis, cultures should be performed for isolation and identification, antibiotic susceptibility, and resistance surveillance. Cultures should also be performed in cases of suspected treatment failures, defined as those that have received CDC-recommended treatment and subsequently has a positive N. gonorrhoeae test result 7 days after treatment and did not engage in sexual activity during those 7 days.[16] In C.S., a NAAT from anal specimen also could be performed because the rectum can serve as a reservoir for gonococci.

TREATMENT

CASE 72-1, QUESTION 6: Compare the various drug regimens used for uncomplicated gonorrhea.

The CDC recommendations are summarized in Table 72-1. Many strains of N. gonorrhoeae exhibit plasmid-mediated resistance to penicillin and tetracycline (penicillinase-producing N. gonorrhoeae [PPNG] and/or tetracycline-resistant N. gonorrhoeae [TRNG], respectively (Fig. 72-2). In addition, significant levels of chromosomally mediated resistance to penicillin, tetracycline, and cefoxitin have been reported.[17] In 2013, all isolates in the Gonococcal Isolate Surveillance Project (GISP) were susceptible to ceftriaxone; therefore, a single dose of intramuscular (IM) ceftriaxone 250 mg is preferred for the treatment of gonorrhea.[18],[19] Cefixime 400 mg orally (PO) as a single dose is no longer recommended as a first-line treatment by the CDC but as an alternative option when ceftriaxone cannot be used. Because of the emergence of high levels of quinolone-resistant N. gonorrhoeae (QRNG), the CDC no longer recommends the use of fluroquinolones, such as ciprofloxacin and ofloxacin, for the treatment of gonorrhea.[2],[20] Because a high percentage of patients with gonorrhea are also coinfected with C. trachomatis, a single dose of azithromycin is recommended to be taken concurrently for a presumed infection (see Case 72-1, Question 7).[2],[19]

Intramuscular spectinomycin, which traditionally had been used in individuals who could not tolerate fluoroquinolones or cephalosporins, is still unavailable from the manufacturer.[21] Although limited data exists for treatment of gonorrhea in patients with cephalosporin or IgE-mediated penicillin allergy, potential alternative treatments are a single dose of gemifloxacin 320 mg PO plus azithromycin 2 g PO, or a single dose of gentamicin 240 mg intramuscularly plus azithromycin 2 g PO.[2],[22] Individuals who have either penicillin or cephalosporin allergies should be desensitized to cephalosporins before treatment begins.[23]

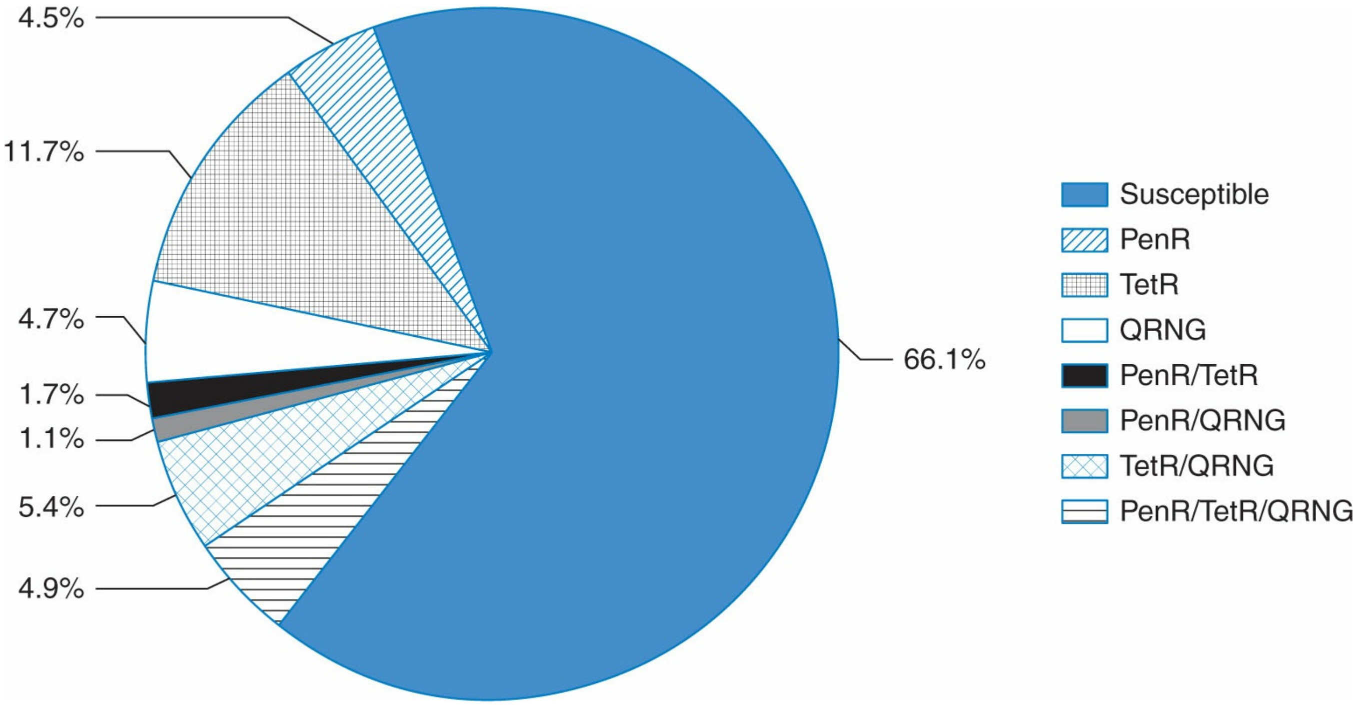

Figure 72-2 Neisseria gonorrhoeae Isolates with Penicillin, Tetracycline, and/or Ciprofloxacin Resistance, Gonococcal Isolate Surveillance Project (GISP), 2013. Note: PenR, penicillinase-producing Neisseria gonorrhoeae and chromosomally mediated penicillin-resistant N. gonorrhoeae; TetR, chromosomally and plasmid-mediated tetracycline-resistant N. gonorrhoeae; and QRNG, quinolone-resistant N. gonorrhoeae.

Ceftriaxone and Other Cephalosporins

Ceftriaxone, a third-generation cephalosporin, is given as a single, small-volume IM injection that eradicates gonorrhea at all anatomic sites and is also safe in pregnancy (U.S. Food and Drug Administration [FDA] pregnancy category B). Ceftriaxone is ineffective against C. trachomatis and in the prevention of postgonococcal urethritis, whereas ofloxacin and levofloxacin for 7 days have similar efficacy to doxycycline.[12] Other injectable cephalosporins (notably ceftizoxime, cefoxitin, and cefotaxime) have been found to be safe and highly effective, but they do not offer any advantage over ceftriaxone for urogenital infections, and their efficacy in pharyngeal infections is not as well-established. A single oral dose of cefixime 400 mg is also effective in curing 92.3% of uncomplicated urogenital and anorectal gonorrhea infections.[2] However, in 2012, the CDC no longer recommended cefixime as a first-line regimen because of concerns about declining cefixime susceptibility among urethral N. gonorrhoeae isolates in the United States during 2006 to 2011.[19] Other oral cephalosporins, such as cefpodoxime and cefuroxime, are not recommended because of inferior efficacy and less favorable pharmacodynamics; however, they are FDA approved to treat uncomplicated N. gonorrhoeae.

Fluoroquinolones

Fluoroquinolones have been routinely used since the 1990s for the treatment of gonorrhea; however, the GISP has continuously documented fluoroquinolone resistance in N. gonorrhoeae isolates, which has necessitated changes in the CDC Sexually Transmitted Disease treatment guidelines (Fig. 72-3). Because of this increased resistance, the CDC no longer recommends ciprofloxacin, levofloxacin, ofloxacin, or other fluoroquinolones for the treatment of gonorrhea. This recommendation also extends to the treatment of gonorrhea-associated conditions, such as PID.[2],[20]

Prescribing Patterns

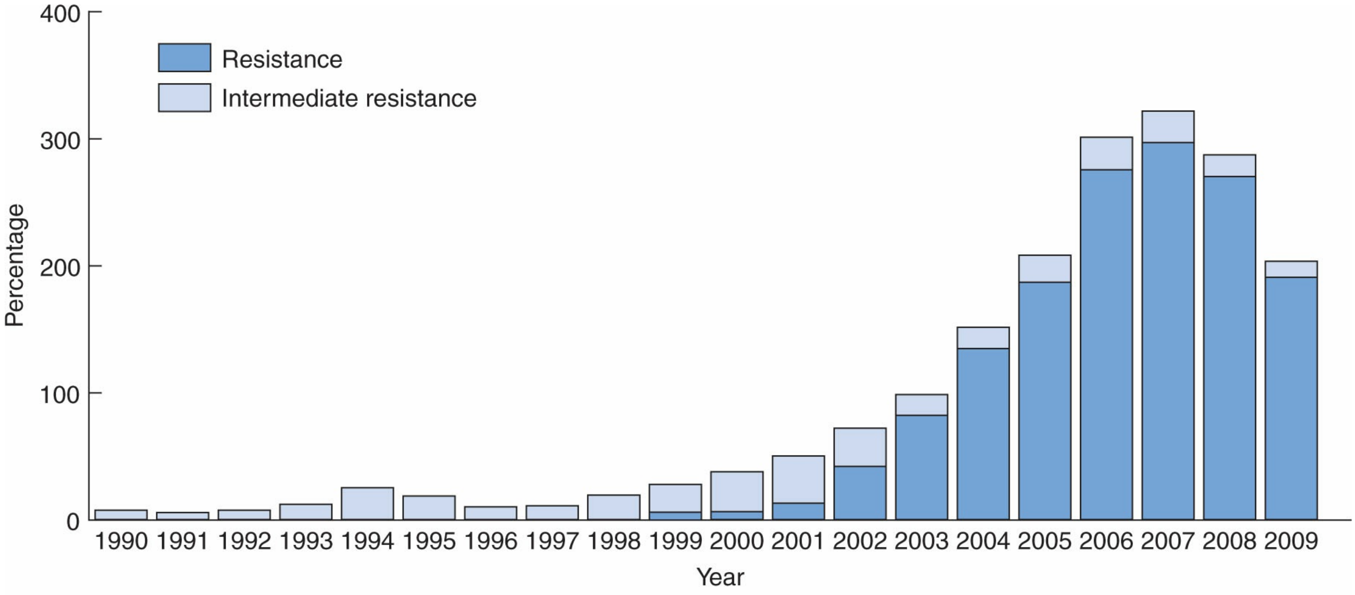
The CDC's 2013 Sexually Transmitted Disease Surveillance Program observed that 96.9% of treated patients received ceftriaxone 250 mg. The number of those treated with cefixime decreased from 5.3% in 2011 to 0.02% in 2013.[4] This decrease in cefixime use was expected as CDC recommendations to avoid use of cefixime at any dose as first-line therapy was issued in 2012. Other most prescribed medications, followed in order by ceftriaxone, azithromycin, "other less frequently used drugs," and cefixime (Fig. 72-4). Dual therapy with azithromycin or doxycycline was prescribed in 95.4% and 4% of those treated with ceftriaxone, respectively.[4]

CASE 72-1, QUESTION 7: How should D.S.'s urethritis be treated? Because C.S. is totally asymptomatic and the results of her cultures are pending, should she be treated empirically? If so, what drug(s) would you recommend?

Because D.S. has gonococcal infection limited to the urethra (uncomplicated), a few treatment regimens are possible, as outlined in Case 72-1, Question 6. Ceftriaxone is the preferred treatment, with cefixime as an alternative, only if ceftriaxone is not available. Quinolones should be avoided because of increased resistance in N. gonorrhoeae and because D.S.'s infection was likely obtained in the Philippines, where quinolone resistance occurs in more than half of all isolates.[20],[24] Patients with gonorrhea may also be coinfected with Chlamydia and therefore presumptive cotreatment with azithromycin 1 g PO as a single dose could be initiated if coinfection is suspected.[19],[25] Although single-dose azithromycin 2 g monotherapy has been used to treat concurrent gonorrhea and Chlamydia, it is more expensive and poorly tolerated because of increased gastrointestinal (GI) side effects and may lead to macrolide-resistant N. gonorrhoeae, or treatment failure.[2]

Sexual Partners

C.S. also should be treated even though she appears asymptomatic. All partners who have had sexual exposure to patients with gonorrhea within 60 days should be treated. If the patient has not been sexually active for 60 days, the most recent sexual partner should be treated. This is especially true when the partner is pregnant because gonorrhea during pregnancy is associated with chorioamnionitis and prematurity, as well as neonatal infection. Pregnant women can be treated safely with cephalosporins and azithromycin for gonorrhea and Chlamydia.



NOTE: Resistant isolates have ciprofloxacin minimum inhibitory concentrations (MICs) ≥1 mcg/mL. Isolates with intermediate resistance have ciprofloxacin MICs of 0.125–0.5 mcg/mL. Susceptibility to ciprofloxacin was first measured in GISP in 1990.

Figure 72-3 Gonococcal Isolate Surveillance Project (GISP)—Percent of Neisseria gonorrhoeae isolates with resistance or intermediate resistance to ciprofloxacin, 1990 to 2009. Source: Centers for Disease Control and Prevention. 2009 Sexually Transmitted Disease Surveillance. Atlanta, GA: US Dept of Health and Human Services; 2010.

Follow-Up

CASE 72-1, QUESTION 8: How does one determine whether the drug therapy of gonorrhea has been effective in D.S. and C.S.?

If recommended therapies are used for treatment of uncomplicated gonorrhea, a test-of-cure is not necessary for either C.S. or D.S. because cure rates are close to 100%.[2] However, a test-of-cure should be done 14 days after treatment in those with pharyngeal infection treated with an alternative treatment regimen.[2] If symptoms persist in D.S., who was treated with ceftriaxone, cultures should be done to determine antibiotic susceptibility, and to rule out other causes of urethritis.

Antibiotic-Resistant Neisseria gonorrhoeae

CASE 72-1, QUESTION 9: D.S. states that he was treated with penicillin in the past for a gonococcal infection. Why are penicillins not prescribed routinely today?

Failure of penicillin to eradicate the gonococcus can be the result of plasmid (e.g., PPNG) or chromosomally mediated resistant Neisseria gonorrhea (CMRNG) antibiotic resistance. PPNG contain plasmids, which determine the production of lactamase, an enzyme that hydrolyzes the lactam ring of penicillin G or ampicillin. Chromosomally mediated resistance does not involve β-lactamase production and often is associated with increased resistance to other β-lactams. The clinical significance of CMRNG is questionable because serum levels of approved antibiotics are achieved far above the minimum inhibitory concentration, such that treatment failure is unlikely. However, to date, CMRNG remain largely susceptible to ceftriaxone. High-level tetracycline resistance is defined by gonococci that carry plasmid-encoded resistance to 16 g/mL or more of tetracycline. These strains are known as TRNG. Although not of major concern in the United States, development of resistance to alternative therapies is a continuing concern.

The first cases of PPNG infection were reported in the United States in 1976. PPNG are especially prevalent in Southeast Asia, the Far East, and West Africa, where the prevalence often exceeds 50%. In the United States, the percent of PPNG strains reached a peak of about 11% in 1991; since then, cases have steadily declined to 0.4% in 2007, according to the CDC's GISP (Fig. 72-2).[26] Strains of TRNG were first identified in 1985, but fortunately most TRNG isolates still are sensitive to β-lactam antibiotics. The use of tetracycline was officially abandoned by the CDC in 1985 and penicillin was abandoned in 1987. In the late 1990s, the number of TRNG and PPNG plus TRNG cases plateaued at about 5% and 1%, respectively. Therefore, because approximately 21% of gonococcal isolates are resistant to tetracycline and/or penicillin within the United States, it is not acceptable to use these agents in the initial management of uncomplicated genital gonorrhea; IM ceftriaxone remains the drug of choice. Antibiotic susceptibility testing is recommended in cases of persistent infection after treatment.

QRNG was first reported in 1990 and was reported to be 0.2% of isolates in the continental United States.[3],[17] In the 2013 GISP report, 11% of isolates from Honolulu, Hawaii, were QRNG, whereas among California sites, 31.8% to 44.4% of isolates were QRNG.[27] N. gonorrhoeae resistance to quinolones has increased almost every year since reporting began in 1990 and has become widespread in the United States, resulting in the CDC recommending against using quinolones for the treatment of gonococcal or related conditions (e.g., PID) acquired in the United States.[12],[20] In 2013, 16.1% of all isolates collected by the GISP demonstrated resistance to ciprofloxacin.[4] Resistance to fluoroquinolones is associated with mutations of GyrA and is commonly identified in strains that produce β-lactamase and strains exhibiting chromosomally mediated resistance to penicillin and tetracycline.[28] N. gonorrhoeae strains may therefore exhibit decreased susceptibility or complete resistance to the recommended dose of quinolones, and the clinical importance of strains with decreased susceptibility is unknown.[29]

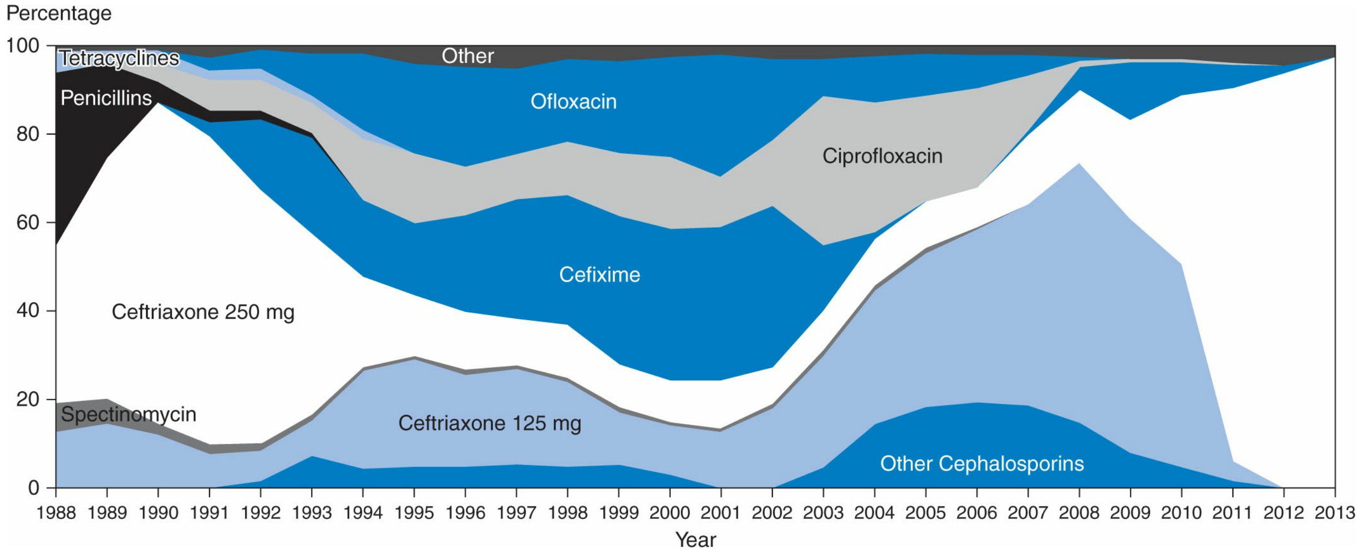


Figure 72-4 Gonococcal Isolate Surveillance Project (GISP)—Drugs used to treat gonorrhea in GISP participants, 1988 to 2013. Note: For 2013, "Other" includes no therapy (0.9%), azithromycin 2 g (1.7%), and other less frequently used drugs (<0.1%).

D.S. was likely infected with N. gonorrhoeae in the Philippines, and QRNG is highly likely; thus, an appropriate cephalosporin antibiotic such as IM ceftriaxone should be recommended. If he had been initially treated with ceftriaxone, the expectation would be that he would be free of gonococcal infection within 3 days. To date, ceftriaxone-resistant strains of N. gonorrhoeae have not been reported in the United States, but GISP data has documented decreased cefixime susceptibility among urethral N. gonorrhoeae isolates.[19]

Anorectal and Pharyngeal Gonorrhea

EPIDEMIOLOGY

CASE 72-2

QUESTION 1: M.B. is a 24-year-old, sexually active, homosexual man with a 2-month history of perianal itching, painful defecation, constipation, a bloody mucoid rectal discharge, and a sore throat. Sigmoidoscopy revealed rectal mucosal inflammation but no apparent ulcers or fissures. Stool examination for parasites was negative and a Venereal Disease Research Laboratory (VDRL) test was nonreactive. Both rectal and pharyngeal cultures revealed N. gonorrhoeae. How does gonorrhea in homosexual men compare with gonorrhea in heterosexual men?

Rectal infection occurs rarely in strictly heterosexual men, whereas in the male homosexual population, anorectal (25%) and pharyngeal (10%–25%) gonococcal infections occur more often.[8],[30] Because pharyngeal[30],[31] and anorectal gonococcal infections are often asymptomatic, a large reservoir of carriers in the homosexual male population may exist and annually screening should be done if they have engaged in receptive oral or anal intercourse in the preceding year. By comparison, very few urethral gonococcal infections are asymptomatic. In addition, data indicate that pharyngeal infections may be an important source of urethral gonorrhea in homosexual men, spread by fellatio.[30],[32]

SIGNS AND SYMPTOMS

CASE 72-2, QUESTION 2: Are M.B.'s signs and symptoms consistent with gonorrhea?

Rectal gonorrhea produces the syndrome of proctitis with anorectal pain, mucopurulent anorectal discharge, constipation, tenesmus, and anorectal bleeding. The differential diagnosis of proctitis in the homosexual male includes rectal infection with N. gonorrhoeae, C. trachomatis, HSV, and syphilis. Proctitis, limited to the distal rectum, should be differentiated from proctocolitis, which is often caused by Shigella species, Campylobacter species, or Entamoeba histolytica in homosexual men. The incidence of rectal gonorrhea and Chlamydia has risen dramatically since 1996.[33] Rectal Chlamydia is often asymptomatic and observed more often than gonorrhea, necessitating testing for both pathogens.[34] Although pharyngeal gonorrhea is often asymptomatic, a review of system and physical exam may reveal a sore throat, pharyngeal exudates, or cervical lymphadenitis.

CASE 72-2, QUESTION 3: How should M.B.'s diagnosis be managed?

TREATMENT

The treatment of choice for patients such as M.B. with anorectal or pharyngeal gonorrhea is ceftriaxone 250 mg IM as a single dose (Table 72-1).[12] Azithromycin should also be given to treat possible coexisting rectal chlamydial infection. Patients, such as M.B., with either anorectal or pharyngeal gonorrhea should be advised to avoid further unprotected sexual activity and should be counseled and tested for infection with HIV.

CASE 72-2, QUESTION 4: What are the alternative regimens for patients with isolated anal or pharyngeal gonorrhea?

Patients with anorectal gonorrhea alone should be treated with ceftriaxone. Oral cefixime is a recommended alternative, but it should not be used as a first-line agent. As with urogenital

infections, alternative regimens for isolated anorectal infection include a single-dose cephalosporin regimen, such as ceftizoxime. Because spectinomycin is unavailable, patients with anorectal gonorrhea, who are allergic to penicillin or cephalosporins, should be desensitized before treatment is initiated. Patients with gonococcal infections of the pharynx should be treated with ceftriaxone; however, infections of this nature are more difficult to eradicate than infections at urogenital and anorectal sites. Treatment for gonorrheal infections at these sites should also be treated with azithromycin for presumptive Chlamydial coinfection.[19]

PREVENTION

CASE 72-2, QUESTION 5: What measures have been used to prevent the sexual transmission of infection?

Condoms, when used properly, seem to provide a high degree of protection against the acquisition and transmission of STDs.[2],[35] Previous studies indicated that the use of the spermicide nonoxynol-9 had activity against gonorrhea and Chlamydia; however, in light of recent evidence suggesting that nonoxynol-9 might actually increase the risk of acquiring HIV and other STDs, the FDA currently requires manufacturers of nonoxynol-9 products to include a warning statement on the product's label that it does not protect against HIV or other STDs.[12],[36] Topical antibacterial agents, urinating, and washing after intercourse are of little value in preventing the transmission of STDs. Douching may increase the risk of other STDs, such as trichomoniasis.[37]

The prophylactic administration of antibiotics immediately before or soon after sexual intercourse is not recommended owing to increased costs and antimicrobial resistance. Use of rapid, specific tests and empiric symptomatic management enhances detection and treatment of gonorrhea.

PELVIC INFLAMMATORY DISEASE

The term PID refers to a variety of inflammatory disorders of the upper female reproductive tract. This term does not denote the primary infection site (the fallopian tubes) nor the causative microorganisms. PID also has been used to connote an infection that occurs acutely when either vaginal or cervical micro-organisms traverse the sterile endometrium and ascend to the fallopian tubes. Acute salpingitis may also be used to describe an acute infection of the fallopian tubes. Therefore, the terms PID and salpingitis are used interchangeably in this discussion to denote an acute infection involving the fallopian tubes.

PID affects approximately 1 million women annually in the United States.[38] However, the National Disease and Therapeutic Index (NDTI) estimates that from 2002 to 2012, the number of initial visit to physicians for PID for women aged 15 to 44 decreased 39.8%.[4] Many cases of acute PID occur by sexual transmission, especially in young women 16 to 24 years, who are more likely to have multiple sexual partners.[39] Risk factors for the development of PID include unprotected sexual intercourse before age 15, douching, BV, sex while menstruating, and smoking.[40] It is unclear whether an intrauterine device (IUD) increases the risk of PID, but it may be prudent to avoid placement when the patient has chlamydial or gonococcal cervicitis.[41] Two-thirds of PID cases resulting in infertility are asymptomatic, and up to one-third are incorrectly diagnosed owing to low specificity of diagnostic techniques. In the United States, infertility occurs in about 12.1% of women after the first episode of PID.[42] The estimated costs for treatment of PID and its sequelae exceeds $4.2 billion annually.[38]

Etiology

Most cases of PID are caused by C. trachomatis and N. gonorrhoeae. Some microorganisms that make up the vaginal flora are also associated with PID, including Gardnerella vaginalis, H. influenzae, and Streptococcus agalactiae. Mycoplasma hominis, Ureaplasma urealyticum, M. genitalium, and cytomegalovirus (CMV) have also been associated with PID, but a causative role is unclear.[12] Up to 70% of cases may be polymicrobial and include M. genitalium and BV.[43] Facultative enteric gram-negative bacilli and a variety of anaerobic bacteria have also been isolated from the upper genital tract of up to 70% of women with acute PID.[43] Women diagnosed with acute PID should be tested for C. trachomatis and N. gonorrhoeae using NAAT and screened for HIV.[2]

Signs and Symptoms

The variations in presentation and nonspecific signs and symptoms of PID make it a complex disease to diagnosis. The onset of symptoms of abdominal pain attributable to PID caused by either gonococci or chlamydia often occurs soon after the menstrual period. Symptoms of PID, if present, are often nonspecific, which can create a delay in or failure of diagnosis. Vaginal discharge, menorrhagia, dysuria, and dyspareunia are commonly associated with PID. Pelvic examination findings include cervical motion tenderness, uterine tenderness, or adnexal tenderness. Temperatures greater than 101°F, abnormal cervical or vaginal mucopurulent discharge, white blood cells (WBC) on saline microscopy of vaginal secretions, elevated erythrocyte sedimentation rate, an elevated C-reactive protein, or laboratory documentation of cervical infection with N. gonorrhoeae or C. trachomatis support a diagnosis of PID.[2] Clinical diagnosis has sensitivity for PID of about 65% to 90%, whereas laparoscopy and a newer technique, transvaginal Doppler ultrasound, are about 100% specific, resulting in the combination of laparoscopy and clinical impression serving as the gold standard.[2],[44],[45] Unfortunately, laparoscopy and Doppler ultrasound are costly and often not readily available for acute cases and they are not diagnostic for endometritis; thus, clinical impression is critical. A key to reducing the incidence of PID may be through active screening of Chlamydia in young, sexually active women.[46],[47]

Clinical Sequelae

An abscess may form in the pelvic or abdominal cavity and in one or both fallopian tubes. Chronic abdominal pain develops in 18% of women with PID and may be the result of pelvic adhesions surrounding the tubes and ovaries. After a single episode of PID, tubal occlusion and fibrosis secondary to fallopian tube inflammation (salpingitis) result in 12% infertility, 25% infertility after two episodes, and 50% infertility after three or more episodes.[42] Other sequelae include ectopic pregnancy (9%) and chronic pelvic pain (18%).[48] The risk of ectopic pregnancy is increased approximately eightfold after one or more episodes of PID.

Diagnosis and Treatment

CASE 72-3

QUESTION 1: H.C., a 19-year-old, sexually active woman, complains of mild dysuria, a purulent vaginal discharge, fever, and moderately severe, bilateral, lower abdominal pain of 3 days duration. Examination confirms uterine and adnexal tenderness, a purulent cervical exudate, and a temperature of 39°C. Laboratory examinations show a nonreactive VDRL and negative urinalysis. A pregnancy test performed was negative. The peripheral WBC count was mildly elevated (11,000/µL) with 70% polymorphonuclear leukocytes. Does H.C. have PID? How should she be treated?

Table 72-2

Antimicrobial Regimens Recommended by the CDC for Treatment of Acute Pelvic Inflammatory Disease

Treatment Setting, Drugs, Schedule	Advantage	Disadvantage	Clinical Considerations
Inpatient (Parenteral) Therapy			
Regimen A			
Cefotetan 2 g IV every 12 hours OR cefoxitin 2 g IV every 6 hours PLUS doxycycline 100 mg IV or PO[a] every 12 hours Continue doxycycline (100 mg PO twice daily) after discharge to complete 14 days of therapy	Optimal coverage of N. gonorrhoeae (including resistant strains) and C. trachomatis	Possible suboptimal anaerobic coverage	Penicillin-allergic patients may also be allergic to cephalosporins; doxycycline use in pregnant patients may cause reversible inhibition of skeletal growth in the fetus and discoloration of teeth in young children

Regimen B			
Clindamycin 900 mg IV every 8 hours PLUS gentamicin loading dose IV or IM (2 mg/kg) followed by a maintenance dose of 1.5 mg/kg every 8 hours[b]	Optimal coverage of anaerobes and Gram-negative enteric rods	Possible suboptimal coverage of N. gonorrhoeae and C. trachomatis	Patients with decreased renal function may not be good candidates for aminoglycoside treatment or may need a dosage adjustment
Alternative Regimen			
Ampicillin/sulbactam 3 g IV every 6 hours PLUS doxycycline 100 mg PO or IV every 12 hours	Optimal coverage of N. gonorrhoeae and C. trachomatis	Inadequate coverage of anaerobes necessitates use of metronidazole or ampicillin/sulbactam	Not appropriate in pregnancy or in young children
Outpatient (Oral) Therapy[c]			
Regimen A			
Ceftriaxone 250 mg IM in a single dose PLUS doxycycline 100 mg PO twice daily for 14 days WITH or WITHOUT metronidazole 500 mg PO twice daily for 14 days OR cefoxitin 2 g IM in a single dose and probenecid, 1 g PO administered concurrently in a single dose PLUS doxycycline 100 mg PO twice daily for 14 days WITH or WITHOUT metronidazole 500 mg PO twice daily for 14 days OR other parenteral third-generation cephalosporins (e.g., ceftizoxime or cefotaxime) PLUS doxycycline 100 mg PO twice daily for 14 days WITH or WITHOUT metronidazole 500 mg PO twice daily for 14 days	Good to excellent coverage of N. gonorrhoeae and optimal coverage of C. trachomatis	Possible suboptimal anaerobic coverage necessitating the addition of metronidazole	Optimal cephalosporin is unclear; more complicated regimen requiring combination of parenteral and oral therapies

[a] Considering the oral bioavailability of doxycycline, PO therapy should be preferentially used over IV.

[b] Single daily dosing (3–5 mg/kg) may be substituted.

[c] Consider for mild-to-moderate acute PID.

Adapted from Workowski KA, Bolan GA; Centers for Disease Control and Prevention (CDC). Sexually transmitted diseases treatment guidelines, 2015. MMWR Recomm Rep. 2015;64(RR-03):1–137.

Although fever and leukocytosis are often absent in mild or subacute PID, these findings in a woman with uterine and adnexal tenderness with cervical exudate increases the likelihood of acute PID. Recommended treatment regimens for PID are listed in Table 72-2 and should be initiated immediately after diagnosis of PID to prevent clinical sequelae; confirmation of the actual pathogen rarely takes place. Patients such as H.C. with mild-to-moderate PID can be hospitalized and treated with parenteral antibiotics; however, clinical efficacy and overall outcomes are equal between parental and oral therapy, and H.C. could also be treated on an outpatient basis. For inpatient treatment, the CDC recommends either intravenous (IV) cefotetan

2 g every 12 hours or IV cefoxitin 2 g every 6 hours for at least 24 hours beyond the first signs of clinical improvement along with doxycycline 100 mg every 12 hours. Once clinical improvement is noted, parenteral therapy may be discontinued and PO doxycycline 100 mg every 12 hours can continue to complete 14 days of therapy. For outpatient treatment, the CDC guidelines recommend either IM ceftriaxone 250 mg as a single dose or IM cefoxitin 2 g as a single dose (with probenecid 1 g PO for one dose) plus PO doxycycline 100 mg twice a day for 14 days with or without PO metronidazole 500 mg twice daily for 14 days.[2] A tetracycline derivative or an alternative agent that is active against C. trachomatis should be included in the treatment of PID; however, monotherapy with a tetracycline is not recommended because of the lack of activity against gram-negative aerobic and anaerobic organisms and N. gonorrhoeae. The addition of metronidazole, which covers anaerobic bacteria, should also be considered; anaerobes have been isolated from the upper reproductive tract of women with PID and may cause tubal and epithelial destruction.[2,49] Metronidazole is widely used by clinicians, because BV is frequently associated with PID.[2] Fluoroquinolones, such as levofloxacin and ofloxacin, are no longer recommended for the treatment of PID because of the increase in prevalence of QRNG in the United States.[20]

Both oral and IV doxycycline have similar bioavailability; therefore, doxycycline should be given PO whenever possible.[2] Substantial clinical improvement is usually seen within 3 days after initiation of therapy. Clindamycin plus gentamicin can be used alternatively in penicillin-allergic and pregnant women.[2] Because H.C. is sexually active, any sexual partners within the previous 60 days (or if >60 days, then the most recent sexual partner) should be empirically treated because of the risk of gonococcal or chlamydial urethritis as well as to reduce the risk of reinfection.[2]

COMPLICATED GONORRHEA

Disseminated Gonococcal Infection

SIGNS AND SYMPTOMS

CASE 72-4

QUESTION 1: S.P., a 28-year-old, sexually active woman, was seen for stiffness and pain of the right wrist and left ankle and fever (38°C). On physical examination, the knee and wrist joints were found to be hot, red, and swollen; papules and pustular lesions were observed on S.P.'s legs and forearms. A latex fixation test for rheumatoid factor was negative. A tap of the right knee yielded an effusion with a WBC count of 34,000/ µL (80% polymorphonuclear leukocytes). Cultures of the skin lesions were negative, but N. gonorrhoeae was isolated from the throat, cervix, blood, and synovial fluid. A chest radiograph, echocardiogram, and electrocardiogram all were normal, and no murmur could be appreciated. Assess S.P.'s clinical presentation.

S.P.'s signs, symptoms, and laboratory findings are consistent with gonococcal bacteremia, which today occurs in less than 1% of women and men with gonorrhea. The most common manifestation of gonococcemia is the gonococcal arthritis–dermatitis syndrome or DGI exhibited by S.P. Symptoms include fever, occasional chills, a mild tenosynovitis of the small joints, and skin lesions; the latter primarily involving the distal extremities are petechial, papular, pustular, and hemorrhagic in appearance.[2]

Diagnosis of DGI is made by NAAT or culture of specimen from routine sites of gonococcal infections (e.g., urethra, cervix, pharynx, and rectum), as well as culture from disseminated sites of infection (e.g., synovial fluid, blood, skin, and CNS). However, blood cultures are positive in only 33% of DGI cases, even when culture samples are obtained early in the course of the infection.[12] The low positive yield from blood cultures may be attributable to the low inoculum or intermittent bacteremic period.

TREATMENT

CASE 72-4, QUESTION 2: How should S.P. be managed? How quickly will she respond to therapy?

Patients like S.P. with gonococcal arthritis and bacteremia should be hospitalized for treatment with ceftriaxone 1 g IV or IM daily until substantial clinical improvement is sustained for 24 to 48 hours, at which time therapy may be switched to an oral agent guided by antimicrobial susceptibility for a total treatment course of at least 7 days (Table 72-3).[2] Initiation of treatment should also include azithromycin 1 g PO in a single dose. Symptoms and signs of tenosynovitis should be improved markedly within 48 hours. Septic gonococcal arthritis with purulent synovial fluid may require repeated aspiration and resolves more slowly.

Table 72-3

Treatment of Disseminated Gonococcal Infection

No Penicillin Allergy[a]
Parenteral
Recommended[b]—Ceftriaxone 1 g IV or IM every 24 hours
Alternative[b]—Cefotaxime 1 g IV q8h or ceftizoxime 1 g IV every 8 hours
Oral[c]
Cefixime 400 mg PO twice daily

[a] Parenteral treatment should be continued for 24 to 48 hours beyond clinical improvement.

[b] Treatment should include a single dose of Azithromycin 1 g PO.

[c] Treat for 7 days after switching from parenteral therapy.

Adapted from Workowski KA, Bolan GA; Centers for Disease Control and Prevention (CDC). Sexually transmitted diseases treatment guidelines, 2015. MMWR Recomm Rep. 2015;64(RR-03):1–137.

CASE 72-4, QUESTION 3: How should gonococcal endocarditis and meningitis be treated?

Treatment of Gonococcal Endocarditis and Meningitis

Gonococcal endocarditis and meningitis, occurring in only 1% to 3% of DGIs, require high-dose IV therapy, such as ceftriaxone (1–2 g IV every 12–24 hours), for 10 to 14 days in the case of meningitis and for at least 4 weeks in the case of endocarditis.[2] Like other gonococcal infections, a single dose of azithromycin 1 g PO should be given.

Neonatal Disseminated Gonococcal Infection: Treatment

CASE 72-4, QUESTION 4: How should neonatal DGI and meningitis be managed?

Neonatal DGI and meningitis can be treated with either ceftriaxone 25 to 50 mg/kg (IV or IM) daily or cefotaxime 25 mg/kg (IV or IM) every 12 hours. Treatment is for 7 days for DGI; however, meningitis requires 10 to 14 days of treatment.[2] Although ceftriaxone is also effective in the treatment of neonatal DGI and meningitis, cefotaxime is considered a safer choice in the neonatal population.

CHLAMYDIA TRACHOMATIS

The rate of reported Chlamydia infections has climbed steadily each year since the 1980s, and it is the most commonly reported STD in the United States. During 1993 to 2012, the reported rate of chlamydial infections increased from 178 to 453.3 cases per 100,000 individuals.[4] This increase may be attributable to the increased development and use of more sensitive screening tests, improved national reporting efforts, or a true increase in the incidence of disease.[12] In 2013, the United States saw the rate of chlamydial infections decrease for the first time to 446.6 cases per 100,000.[4] Women are 3 times more likely than men to be infected with Chlamydia—623.1 cases versus 262.6 cases per 100,000 individuals, respectively, in 2013. However, from 2009

---

to 2013, the infection rate among men increased 21% compared with 6.2% in women. The highest rate of infection is in women 15 to 19 years (3,043.3 cases per 100,000 females) and in men 20 to 24 years (1,325.6 cases per 100,000 males).[4] If left untreated, chlamydial infection in women can lead to serious sequelae, such as PID, ectopic pregnancy, and infertility. Asymptomatic infection is also observed in both men and women; however, routine screening is recommended for sexually active women up to 25 years of age and older women with risk factors for infection (e.g., multiple sexual partners or having a new sexual partner). Screening sexually active men for C. trachomatis can be considered in settings or populations with a high prevalence of the infection (e.g., MSM populations).[2]

C. trachomatis, an intracellular obligate organism, can be diagnosed either by culture, direct immunofluorescence assay (DFA), enzyme immunoassay (EIA), or NAAT of endocervical or male urethral swabs.[12] However, C. trachomatis is a difficult organism to demonstrate in clinical specimens because cell culture techniques are not readily available to the practitioner. Because few practitioners have access to facilities for isolation of C. trachomatis, most chlamydial infections are diagnosed and treated based on clinical impression and laboratory techniques. Nonculture diagnostic tests, such as NAATs, DFAs, and EIAs, are generally sensitive methods for detecting C. trachomatis. Ligase chain reaction and PCR are two NAATs with wide commercial availability, are relatively simple to use, can be performed using urine or genital swab specimens, and are more sensitive than non-NAATs.[15] NAATs are approximately 20% to 35% more sensitive than EIAs and DFAs and are the recommended test method for detection of C. trachomatis in men and women with and without symptoms.[2],[16] A test-of-cure is not necessary unless patient compliance is questionable, symptoms persist, or reinfection is suspected. Repeat testing with NAATs fewer than 3 weeks after initiation of treatment is not recommended because false-negative results may occur as a result of undetectable C. trachomatis organisms. Moreover, false positives may occur with repeat NAATs with the continued excretion of dead organisms.

A variety of clinical syndromes are caused by C. trachomatis, including cervicitis, urethritis, bartholinitis, endometritis, salpingitis, and perihepatitis in women, and urethritis, epididymitis, prostatitis, proctitis, and Reiter syndrome in men.[12] The spectrum of chlamydial infections closely resembles those caused by the gonococcus, which is why many patients presenting with these syndromes are treated with drugs effective against both organisms.

There is controversy in how C. trachomatis is cultured and what the in vitro results mean clinically, especially in the 10% to 15% of cases that fail treatment.[50] The CDC thus uses cure rates instead of microbial susceptibilities to make treatment recommendations. Only azithromycin and doxycycline have 97% and 98% cure rates, respectively.[2],[51] Alternatives include erythromycin, ofloxacin, and levofloxacin. Other quinolones should not be used because they have not been evaluated adequately or are not reliably effective.[2]

Nongonococcal Urethritis

ETIOLOGY

CASE 72-5

QUESTION 1: T.K., a 26-year-old, sexually active man, complains of mild dysuria and a mucoid-like urethral discharge beginning 15 days after his last intercourse. He has no fever, lymphadenopathy, penile lesions, or hematuria. A Gram stain smear of an anterior urethral specimen showed 20 polymorphonuclear neutrophilic leukocytes (PMNs) per oil immersion (1,000) field and no gram-negative diplococci. What pathogens are associated with nongonococcal urethritis (NGU)?

In the United States, NGU is the most common STD in men.[52],[53] C. trachomatis is a frequent cause of NGU, representing 15% to 40% of all cases. Other agents that have been associated with NGU include M. genitalium, T. vaginalis, HSV, and adenovirus; however, the cause for the majority of NGU cases is unknown.[12] The variety of pathogens and disparity among identification techniques require sound clinical judgment and an algorithmic laboratory testing approach to accurately identify and treat the cause. A NAAT, if available, should be performed to rule out the presence of C. trachomatis and N. gonorrhoeae.

SIGNS AND SYMPTOMS

CASE 72-5, QUESTION 2: Describe the clinical presentation of a person with NGU. Is T.K.'s presentation consistent with NGU? How does one differentiate between NGU and gonococcal urethritis?

T.K.'s presentation is typical. Compared with gonococcal urethritis, NGU typically produces less severe and less frequent dysuria and less penile discharge. Chlamydial urethral infection is completely asymptomatic more often than gonococcal urethral infection. The incubation period for gonococcal urethritis is 2 to 7 days, whereas the incubation period for NGU is typically 2 to 3 weeks.

Nonetheless, NGU and gonococcal urethritis cannot be reliably differentiated solely on the basis of symptoms and signs. If there is objective evidence of a urethral discharge (expressed by milking the urethra), a Gram stain with ≥2 WBCs per oil immersion field in the urethral secretion, positive leukocyte esterase test demonstrating 10 WBCs per high-power field, the diagnosis of NGU is made by excluding the presence of N. gonorrhoeae by Gram stain and/or culture.

TREATMENT

CASE 72-5, QUESTION 3: How should T.K. be treated?

If C. trachomatis cannot be ruled out, therapy with azithromycin 1 g PO for one dose or doxycycline 100 mg PO twice daily for 7 days should be ordered. Compared to doxycycline, M. genitalium responds better to azithromycin as doxycycline does not effectively eradicate M. genitalium.[2] Azithromycin also has the advantage of a single-dose regimen, which may aid in patient compliance. Erythromycin base 500 mg PO 4 times a day or erythromycin ethylsuccinate 800 mg PO 4 times a day for 7 days are alternative CDC-approved regimens. Additionally, ofloxacin 300 mg PO twice daily or levofloxacin 500 mg PO every day for 7 days are other alternatives, but they offer no significant advantages compared with the previously mentioned agents, may not treat U. urealyticum adequately, and are significantly more expensive.[2],[54] Ciprofloxacin should be avoided because treatment failures have been reported.[55] Patient counseling should emphasize the need for abstinence from sexual intercourse at least until the prescribed course of therapy has been completed (or 7 days after single-dose therapy) by the patient and his sexual partner(s).[2] There is some indication that the proportion of NGU caused by C. trachomatis is declining, potentially being replaced by an increased proportion of U. urealyticum, which is variably cured at 2 weeks by azithromycin (73%) and doxycycline (65%).[56]

Recurrent Infection

CASE 72-5, QUESTION 4: T.K. was treated with doxycycline 100 mg twice daily for 7 days. He remained asymptomatic for 14 days after completion of his therapy, when he again noticed similar symptoms of dysuria and a mucoid-like urethral discharge. How should T.K.'s recurrent infection be treated?

The major problem encountered in the treatment of NGU is the high rate of recurrent infections. Men receiving treatment should follow-up if symptoms persist or recur after completion of therapy. Approximately 20% to 60% of patients experience recurrent or persistent urethritis within 1 to 2 weeks after treatment.[57] The rate of recurrence is highest in patients with idiopathic urethritis, that is, those not infected with C. trachomatis or U. urealyticum. Recurrence suggests reexposure to an untreated partner, whereas persistent urethritis (without improvement during therapy) suggests the presence of other organisms, including M. genitalium, U. urealyticum, or T. vaginalis.[2],[58],[59] NGU that persists or recurs should be retreated with the initial regimen if the patient was not compliant or the sexual partner was not treated. For patients with persistent symptoms, who were compliant with the initial regimen and were not reexposed, the CDC recommends using a single 1 g dose of azithromycin if not used for the initial episode, or moxifloxacin 400 mg PO daily for 7 days if the patient has failed azithromycin.[2]

Men with acute epididymitis often have chlamydial or gonococcal infection, particularly if they are younger than 35 years of age or have a urethral discharge. Escherichia coli and Pseudomonas species are common pathogens in homosexual men. In older men, sexually transmitted epididymitis is less common and is more commonly caused by urinary tract instrumentation, surgery, systemic disease, or immune suppression.[2] If testicular tenderness is present with urethritis, and the clinical impression is consistent with epididymitis caused by Chlamydia or gonorrhea, the CDC recommend a single dose of ceftriaxone 250 mg IM plus doxycycline 100 mg PO twice for 10 days. For acute epididymitis caused by enteric organisms or with a negative gonococcal culture or NAAT, ofloxacin 300 mg PO twice daily or levofloxacin 500 mg PO once daily for 10 days may be used.[2],[49] In men who practice insertive anal sex, where the most likely cause of acute epididymitis is caused by Chlamydia, gonorrhea, and enteric organisms, the CDC recommends ceftriaxone 250 mg IM in a single dose plus levofloxacin 500 mg PO daily or ofloxacin 300 mg PO BID for 10 days.[2]

SEXUAL PARTNERS

CASE 72-5, QUESTION 5: A.C., T.K.'s girlfriend, comes into the clinic 3 weeks after T.K.'s last visit. She is worried that she may have a similar infection, although she has no signs or symptoms. What clinical manifestations of chlamydial infections are seen in women? Should A.C. be treated for suspected chlamydial infection?

In the absence of cultures for Chlamydia, empirical treatment against chlamydia of women who are sexual partners of men with NGU is recommended. Many partners are asymptomatic but from 30% to 70% are culture positive if tested. A.C. should be examined carefully for mucopurulent cervicitis and salpingitis. Although many women with chlamydial infection of the cervix are asymptomatic, up to one-quarter have evidence of mucopurulent discharge.[60] A Gram stain of appropriately collected mucopurulent endocervical discharge from patients with Chlamydia infection shows many PMNs and no gonococci.

Regardless of findings, treatment should be initiated with the same azithromycin or doxycycline regimen used for NGU. However, if A.C. is pregnant, tetracyclines and fluoroquinolones should be avoided. Azithromycin 1 g PO as a single dose or amoxicillin 500 mg PO 3 times a day for 7 days could be used instead. Alternatively, either erythromycin base 500 mg PO 4 times a day for 7 days, erythromycin base 250 mg PO 4 times a day for 14 days, erythromycin ethylsuccinate 800 mg PO 4 times a day for 7 days, or erythromycin ethylsuccinate 400 mg PO 4 times a day for 14 days can be used.[2] Erythromycin estolate should be avoided in pregnancy because of the increased risk of hepatotoxicity. Azithromycin is safe and effective during pregnancy.[61],[62] High rates of GI side effects limit the use of erythromycin. In pregnant women, a repeat NAAT is recommended 3 weeks after completion of therapy to ensure therapeutic cure.[2] Coinfection with Chlamydia is common in heterosexual men and women with gonorrhea. Therefore, drug regimens effective against both organisms are recommended in patients with gonorrhea to prevent postgonococcal chlamydial morbidity (epididymitis, mucopurulent cervicitis, salpingitis) and to reduce the genital reservoir of C. trachomatis.

Lymphogranuloma Venereum

ETIOLOGY AND SIGNS AND SYMPTOMS

CASE 72-6

QUESTION 1: S.F., a 32-year-old male student who reports having sex with men, presents to the STD clinic with a chief complaint of pain and swelling in the groin. He reports the appearance of a small ulcer on his penis about 2 weeks ago, which resolved rapidly. On examination, he has a bubo (inflammatory swelling of one or more lymph nodes in the groin) with surrounding erythema on his right side. S.F. also has a fever (39°C). Laboratory findings are remarkable for a mild leukocytosis (WBC count, 12,000 cells/μL). What organisms are responsible for lymphogranuloma venereum (LGV)? Describe its clinical course. What subjective and objective manifestations in S.F. are consistent with LGV?

LGV or Nicolas–Favre disease has historically been considered a rare disease in the United States and other developed nations; however, outbreaks have been recently reported in The Netherlands and Great Britain as well as in the United States in New York, Texas, and San Francisco. [63],[64] Since 2003, the number of cases of LGV, especially proctocolitis, in MSM in developed countries has been increasing.[65],[66] The cause of LGV is usually C. trachomatis serovars L1, L2, or L3, which are different from those serovars responsible for chlamydia urethritis.[67] Three stages of LGV infection are recognized in heterosexual men.[68]

Stage I is characterized by a small genital papule or vesicle that appears between 3 and 30 days after exposure. The patient usually is asymptomatic; the ulcer heals rapidly and leaves no scar. This primary lesion is consistent with that reported by S.F. Many patients with LGV recall no primary lesion. Stage II is characterized by acute, painful lymphadenitis with bubo formation (the inguinal syndrome); it is often accompanied by pain and fever, as illustrated by S.F. Without treatment, the buboes may rupture, forming numerous sinus tracts that drain chronically. Adenopathy above and below the inguinal ligament results in the “groove sign.” Healing occurs slowly, and most patients suffer no serious sequelae. Patients in this stage may also present with an anogenitorectal syndrome, which is accompanied by proctocolitis and hyperplasia of intestinal and perirectal lymphatic tissue. Stage III is characterized by perirectal abscesses, rectovaginal fistulae (in women), rectal strictures, and genital elephantiasis.[68] Appropriate treatment of stage II LGV usually prevents these late complications.

An acute anorectal syndrome of LGV occurs in homosexual men who acquire the infection through rectal receptive intercourse. In these cases, a primary anal ulcer may be noted with associated inguinal adenopathy (anal lymphatics drain to inguinal nodes). Subsequently, acute hemorrhagic proctocolitis occurs with tenesmus, rectal pain, constipation, and a mucopurulent, bloody rectal discharge. Rectal biopsy may show granulomatous colitis, mimicking Crohn’s disease. Perirectal pelvic adenopathy also occurs.

TREATMENT

CASE 72-6, QUESTION 2: How should S.F. be treated?

Current CDC recommendations for LGV include doxycycline 100 mg PO twice daily or erythromycin base 500 mg PO 4 times a day for 21 days.[2] Surgical intervention may be needed for later forms of the disease. Azithromycin 1 g weekly for 3 weeks may be effective, as well as fluoroquinolones, but clinical data on its use are lacking.[2]

SYPHILIS

Epidemiology

Syphilis is caused by the spirochete, Treponema pallidum. The rates of primary and secondary syphilis in the United States increased in the late 1980s secondary to crack cocaine use (and associated unsafe sex practices), but from 1990 to 2000 the rates have decreased to those reported in 1941 when reporting began, representing a 89.7% decrease since 1990.[4],[69],[70] However, the number of cases of primary and secondary syphilis have steadily risen since 2000, reaching a high of 17,375 cases in 2013.[4] Another concern is that syphilis facilitates the transmission of HIV, and a high proportion of syphilis is reported in HIV-positive MSM.[4],[71] Since 2008, the rates of congenital syphilis have not increased until 2013, when 348 cases were reported to the CDC representing 8.7 cases per 100,000 individuals, a 0.3% increase from 2012 (Fig. 72-5).[3] This increase was attributable to the increase in the rate of primary and secondary syphilis cases in the West among females during 2010 to 2013. The Healthy People 2020 (HP) goals for primary and secondary syphilis among women is 1.4 cases per 100,000 individuals and among men it is 6.8 cases per 100,000 individuals (Fig. 72-6).[5]

The clinical manifestations of syphilis have not changed appreciably since their first description. However, early diagnosis, treatment, and greater physician/patient awareness of the disease have reduced the incidence of its severe forms. Penicillin continues to be the mainstay of therapy.

Clinical Stages

CASE 72-7

QUESTION 1: D.M., a 27-year-old homosexual man, presents to the STD clinic with complaints of malaise, headache, and fever of 4 days' duration. He also reveals that he had a sore on his penis about 8 weeks ago, but it has since resolved. Upon examination, he is afebrile and has a widespread maculopapular skin rash that involves the soles of his feet; general lymphadenopathy also is appreciated. Medical history is unremarkable except for one episode of gonorrhea 2 years ago that was treated with procaine penicillin. Laboratory findings include a normal peripheral WBC count, a negative serology for HIV antigen, and a positive rapid plasma reagin (RPR) test and fluorescent treponemal antibody absorption (FTA-ABS) test. Describe the clinical course of syphilis. Are D.M.'s symptoms consistent with this infection?

PRIMARY STAGE

The average incubation period for syphilis is 3 weeks and ranges from 10 to 90 days.[72] During this incubation period, T. pallidum can be demonstrated in the lymph and blood. The primary chancre develops at the site of inoculation as a painless papule that becomes ulcerated and indurated. The ulcer is nontender and filled with spirochetes. The chancre usually involves the penis in the heterosexual male; the penis or anus in the homosexual male; and the vulva, perineum, or cervix in the female. Occasionally, the lip or tongue is involved. Regional lymph nodes are enlarged, firm, and nontender. Unfortunately, the typical chancre described earlier often is missed, particularly in women or homosexual men.[73] Without treatment, the primary chancre resolves spontaneously, usually in 2 to 6 weeks. The differential diagnosis of genital ulcers also includes chancroid and genital herpes. Like chancroid, genital herpes produces painful, superficial, nonindurated ulcers with tender inguinal adenopathy. However, unlike chancroid, lesions of genital herpes characteristically proceed through a vesicular state and often are associated with urethritis, cervicitis, and constitutional symptoms, such as fever and chills. Syphilis can be differentiated from herpes by a nonpainful versus painful lesion, a papular versus vesicular appearance, and single versus multiple lesions. Chancroid is more difficult to differentiate from syphilis, although chancroid tends to have a more-tender lesion, jagged border, and striking inguinal lymphadenopathy.[72]

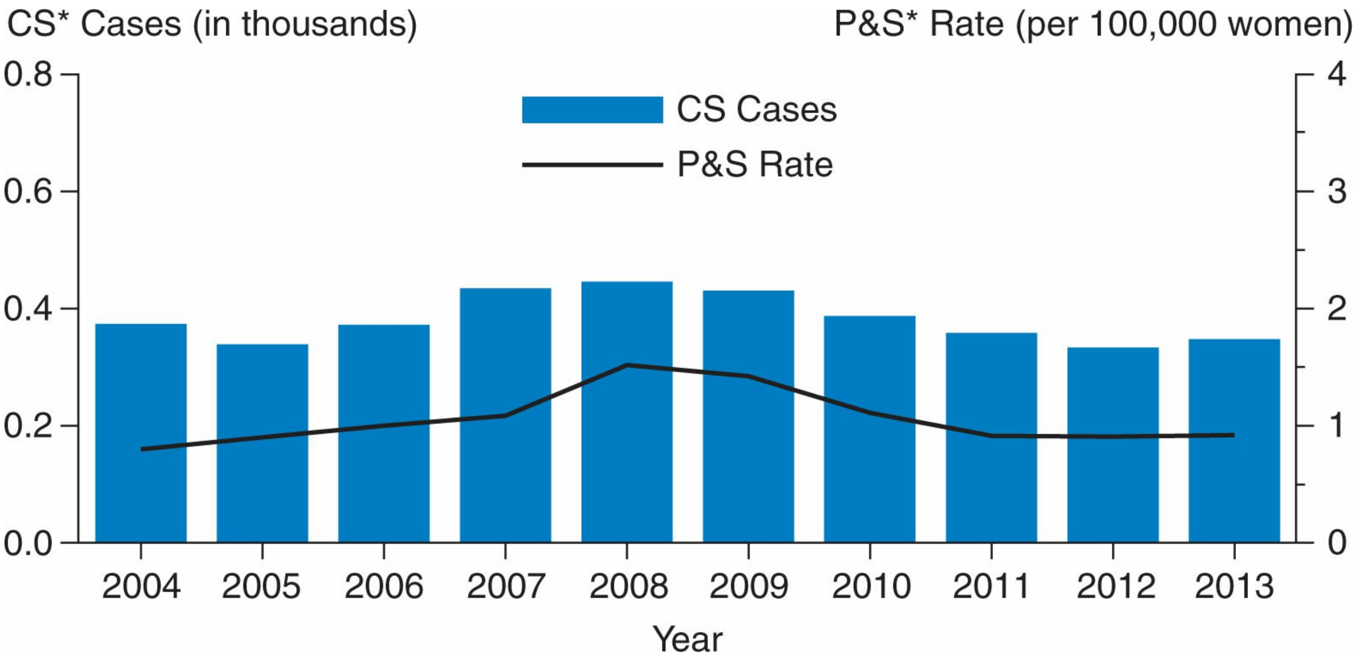

Figure 72-5 Congenital syphilis—Reported cases among infants by year of birth and rates of primary and secondary syphilis among women, 2004 to 2013. Reprinted from Centers for Disease Control and Prevention.

Sexually Transmitted Disease Surveillance 2013. Atlanta, GA: US Dept of Health and Human Services; 2014.

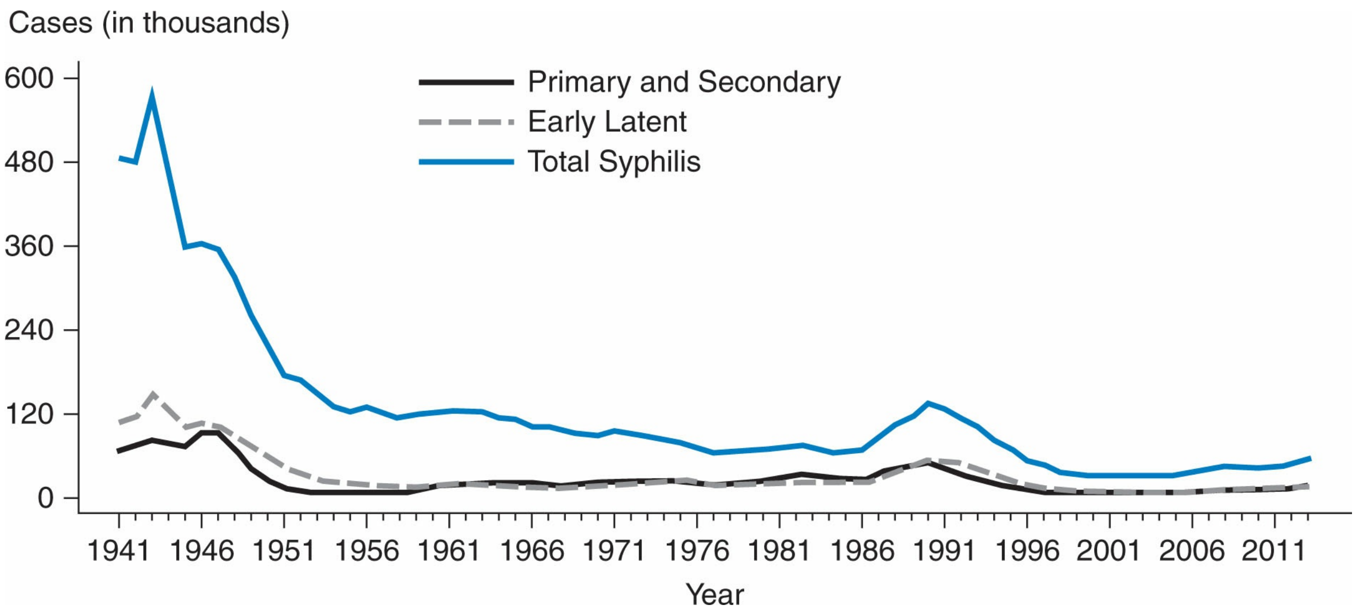

Figure 72-6 Syphilis—Reported Cases by Stage of Infection, United States, 1941 to 2013. Note: the Healthy People 2020 target for primary and secondary syphilis is 1.4 new cases per 100,000 for females and 6.8 new cases per 100,000 for males. Reprinted from Centers for Disease Control and Prevention. Sexually Transmitted Disease Surveillance 2013. Atlanta, GA: US Dept of Health and Human Services; 2014.

SECONDARY STAGE

Approximately 6 weeks after a chancre first appears, the untreated patient manifests signs and symptoms of the secondary stage of syphilis. This stage is currently evidenced by D.M. Skin lesions of secondary syphilis may erupt in a variety of patterns and are usually widespread in distribution. A macular lesion is often the earliest manifestation in this stage. The lesion is round or oval, occurs primarily on the trunk, and is rose or pink in color. As lesions mature, they become papular or nodular with scaling (the so-called papulosquamous rash). The differential diagnosis of diffuse papulosquamous rashes includes psoriasis, pityriasis rosea, and lichen planus. In syphilis, the palms and soles are characteristically involved, and oral lesions (mucous patches) may occur. Generalized lymphadenopathy usually is present, and patchy alopecia may be seen. The most infectious lesion of secondary syphilis is condyloma latum. Condylomata lata are characteristically wet, indurated lesions occurring primarily in the perineum or around the anus as a result of direct spread from the primary lesion. Laboratory studies sometimes reveal anemia, leukocytosis, or an increased erythrocyte sedimentation rate. Other manifestations of secondary syphilis include mild hepatitis, aseptic meningitis, uveitis, neuropathies, and glomerulonephritis.[74]

LATENT STAGE

By definition, untreated, asymptomatic persons with serologic evidence for syphilis have latent syphilis. The latent stage is divided into two phases: the early latent (<1 year's duration) and late latent (>1 year's duration). In the Oslo study of patients with untreated syphilis, 25% experienced secondary relapses, usually within the first year.[75] Patients who relapse to the secondary stage are infectious; those in the late latent stage are not infectious and are immune to reinfection with T. pallidum.

TERTIARY STAGE

Serious morbidity and mortality are caused by pathologic progresses involving the skin, bones, central nervous system, and cardiovascular system. Infectious granulomas (gummas), the characteristic lesions of tertiary syphilis, are observed infrequently. Most gummas respond quickly to specific therapy, although if critical organs are involved (heart, brain, liver), they can be fatal.[76] The most common manifestations of syphilitic cardiovascular disease are aortic insufficiency and aortitis, with aneurysm of the ascending aorta.

Neurosyphilis may be classified as asymptomatic early or late, meningeal, parenchymatous, or gummatous. Although neurosyphilis has been a rare complication for more than 40 years because of the widespread of use of penicillin, syphilitic meningitis, an early form of neurosyphilis, may be more common in HIV-positive patients.[72],[77] Late neurosyphilis may be asymptomatic or accompanied by a variety of manifestations; the most common syndromes are meningovascular syphilis, general paresis, tabes dorsalis (locomotor ataxia), and optic atrophy. In patients with asymptomatic neurosyphilis, examination of the cerebrospinal fluid (CSF) typically reveals mononuclear pleocytosis, an elevated protein concentration, and a positive VDRL reaction.

Patients with asymptomatic neurosyphilis are at increased risk for experiencing neurologic disease. Meningovascular syphilis, accounting for almost 38% of all cases of neurosyphilis, typically begins abruptly with hemiparesis or hemiplegia, aphasia, or seizures.[78] General paresis is characterized by extensive parenchymal damage and includes abnormalities associated with the mnemonic PARESIS (personality, affect, reflexes [hyperactive], eye [Argyll Robertson pupil], sensorium [hallucination, delusions, illusions], intellect [decreased recent memory, calculations, judgment], and speech). Tabes dorsalis occurs after demyelinization of the spinal cord. Symptoms observed include an ataxic, wide-based gait and foot slap; paresthesias; bladder irregularities; impotence; areflexia; and loss of position, deep pain, and temperature sensation. The Argyll Robertson pupil, seen in both paresis and tabes dorsalis, is a small, irregular pupil that reacts to accommodation but not to light.

Laboratory Tests

CASE 72-7, QUESTION 2: Evaluate D.M.'s laboratory findings.

DARK-FIELD EXAMINATION

Exudate expressed from the chancre or from condyloma latum is examined with a dark-field microscope. The diagnosis of syphilis is made if spirochetes with characteristic corkscrew morphology and mobility are present. Dark-field examination is the most specific and sensitive method but only with an experienced microscopist.[79],[80] Three dark-field examinations on consecutive days should be performed before considering the test negative in suspected primary syphilis. This technique and other methods, such as DFA and PCR, which detect T. pallidum directly from exudate or tissue are definitive diagnostic methods for syphilis.

SEROLOGIC TESTS

Serologic tests become reactive during the primary stage, but they may be negative at the time of presentation with primary syphilis. When the history or examination suggests primary syphilis, a VDRL should be sent to the laboratory, or an RPR test should be performed in the clinic (see discussion on nontreponemal tests, next). If initial serology and dark-field examinations are negative, the serology should be repeated in 1 to 4 weeks to exclude primary syphilis. If the dark-field examination is positive, an RPR may still be ordered to establish a baseline for follow-up after treatment.

Serologic tests are uniformly positive in secondary syphilis.[72] Two types of tests are used for the serodiagnosis of syphilis: nontreponemal tests, which measure serum concentrations of reagin (antibody to cardiolipin), and treponemal tests, which detect the presence of antibodies specific for T. pallidum.

Nontreponemal Tests

Nontreponemal tests are not specific for T. pallidum but can be quantified. They are inexpensive and useful for screening large numbers of people. The most widely used nontreponemal tests are the VDRL test and the RPR Card Test. The RPR test is the most widely used because it is simpler to perform than the VDRL. Although they are equally valid assays, results of the VDRL and RPR are not interchangeable; thus, the same test should be used throughout the posttreatment monitoring period.[2],[81]

The result reported in the quantitative VDRL test is the most dilute serum concentration with a positive reaction. This test may be used to follow the decline in VDRL titer after effective therapy (see Case 72-7, Question 5). In some individuals, a serofast reaction occurs in which nontreponemal antibodies may remain at a low titer for up to their entire lives. When false-positive tests occur, the titer usually is low (e.g., VDRL or RPR titer of 1:8).[82] In secondary syphilis, sensitivity of the RPR and VDRL approach 100% owing to the high antibody concentrations.[83]

Treponemal Tests

Specific treponemal tests, such as FTA-ABS, T. pallidum particle agglutination assay (TP-PA), and various EIAs, confirm a positive nontreponemal test. The FTA-ABS test is the most commonly used treponemal test. Because treponemal tests are relatively difficult and expensive to perform, they are not traditionally used for screening.

Treatment

CASE 72-7, QUESTION 3: How should D.M. be treated?

The CDC recommends penicillin G for the treatment of all stages of syphilis (Table 72-4).[2] Every effort should be made to rule out penicillin allergy before choosing alternative agents. Considering that penicillin-resistant T. pallidum has never been observed, treatment regimens for syphilis have changed relatively little during the years.

As shown in Table 72-4, recommended therapy for primary, secondary, or latent syphilis (with negative findings in the CSF) of less than 1 year's duration is a single, IM 2.4 million-unit dose of benzathine penicillin G. If penicillin is contraindicated, tetracycline 500 mg PO 4 times a day or doxycycline 100 mg PO twice a day for 14 days are the main alternatives. If the patient is allergic to penicillin, is not pregnant, and cannot receive tetracycline or doxycycline, a 10- to 14-day regimen of ceftriaxone 1 g IM or IV every day or a single 2 g dose of azithromycin are options.[2] The use of erythromycin as an alternative is no longer recommended by the CDC because of its poor efficacy. The optimal dose, duration, and efficacy of these alternative regimens are not well-defined, necessitating close follow-up of patients. However, recent studies have shown that azithromycin 2 g PO as a 1-time dose is at least equivalent to benzathine penicillin G.[84],[85] Skin testing should be performed for individuals who claim allergy to penicillin. If the patient is truly allergic, he or she should be desensitized.[2] Late latent syphilis (>1 year's duration) and tertiary syphilis (gummas or cardiovascular syphilis) are treated with IM benzathine penicillin G (50,000 units/kg, up to 2.4 million-units) weekly for a total of 3 weeks.[2]

NEUROSYPHILIS

CASE 72-7, QUESTION 4: Would D.M.'s treatment differ if his CSF had tested positive for syphilis?

Neurosyphilis can present at any stage of syphilis. When conventional IM doses of benzathine penicillin G are administered, measurable levels of penicillin are not obtainable in the CSF. However, this does not mean that penicillin does not concentrate in meningeal tissue.[86] Treatment failures, as well as late clinical progression to neurosyphilis, can occur after treatment with the recommended IM regimen. After one dose, benzathine penicillin reaches peak plasma concentrations slower (13–24 hours) but with more prolonged treponemicidal plasma concentrations (7–10 days) when compared with procaine penicillin (1–4 hours to peak; 12–24 hour treponemicidal plasma concentrations).[86] Reports of benzathine penicillin failures in the 1970s has resulted in the CDC recommending treatment with aqueous crystalline penicillin G, 3 to 4 million-units IV every 4 hours, or 18 to 24 million-units per day continuous infusion for 10 to 14 days. Alternatively, neurosyphilis can be treated with concurrent procaine penicillin (2.4 million-units IM daily) and probenecid (500 mg PO 4 times a day) for 10 to 14 days. Some experts add benzathine penicillin G (2.4 million-units IM once a week for up to 3 weeks) after the completion of aqueous penicillin G or procaine penicillin.[2] Penicillin-allergic patients should be skin tested to confirm allergy and, if confirmed, the patient should be desensitized and treated with an appropriate penicillin regimen. Some data suggest that ceftriaxone 2 g IM or IV daily for 10 to 14 days can be used as an alternative in patients whose concern for cross-sensitivity between ceftriaxone and penicillin is negligible.[2] Alternatively, the World Health Organization recommends penicillin-allergic nonpregnant patients receive either doxycycline 200 mg PO twice a day or tetracycline 500 mg PO 4 times a day for 30 days.[87]

FOLLOW-UP

CASE 72-7, QUESTION 5: D.M. was treated with a single IM dose of benzathine penicillin (2.4 million-units). How should his response to therapy be monitored?

Table 72-4

Treatment Guidelines for Syphilis

Stage	Recommended Regimen	Alternative Regimen
Early (primary, secondary, or early latent)[a]	Benzathine penicillin G 2.4 million-units single dose IM	Doxycycline 100 mg PO BID for 14 days or Tetracycline 500 mg PO QID for 14 days or Ceftriaxone 1 g IM/IV every day for 8 to 10 days or Azithromycin 2 g PO × 1 dose
Late latent or latent syphilis of unknown duration	Lumbar puncture	Lumbar puncture
	If CSF normal: benzathine penicillin G 2.4 million-units/week × 3 weeks IM	If CSF normal: doxycycline 100 mg PO BID for 28 days or Tetracycline 500 mg PO QID for 28 days
	If CSF abnormal: Treat as	If CSF abnormal: treat as

	neurosyphilis	neurosyphilis
Neurosyphilis[b] (asymptomatic or symptomatic)	Aqueous crystalline penicillin G 18–24 million-units IV every day × 10–14 days[c]	Procaine penicillin 2.4 million-units IM daily plus probenecid 500 mg PO QID, both for 10–14 days
Congenital	Aqueous crystalline penicillin G 100,000–150,000 units/kg/day, administered as 50,000 units/kg/dose IV q12h during the first 7 days of life, and every 8 hours thereafter for a total of 10 days[d]	If CSF normal: benzathine penicillin G 50,000 units/kg/dose IM in a single dose
	Procaine penicillin G 50,000 units/kg/dose IM a day in a single dose for 10 days	
Syphilis in pregnancy	According to stage	According to stage

[a] Some experts recommend repeating this regimen after 7 days for HIV-infected patients.

[b] Because of the shorter duration of therapy as compared with latent syphilis, some experts recommend giving benzathine penicillin G, 2.4 million-units/week for up to 3 weeks, after the completion of these neurosyphilis regimens to provide a comparable total duration of therapy.

[c] Administered as 3–4 million-units IV every 4 hours or continuous infusion.

[d] All infants born to women treated during pregnancy with erythromycin must be treated with penicillin at birth.

Adapted from Workowski KA, Bolan GA; Centers for Disease Control and Prevention (CDC). Sexually transmitted diseases treatment guidelines, 2015. MMWR Recomm Rep. 2015;64(RR-03):1–137.

Physical examination and a quantitative VDRL or RPR test for primary and secondary syphilis should be repeated at least 6 and 12 months after therapy.[2] Retreatment should be considered when the RPR or VDRL titer does not decline fourfold in 6 months. Patients with HIV coinfection should receive periodic serologic testing.[72] Patients with latent syphilis should be retested 6, 12, and 24 months after treatment. Close serologic monitoring is necessary if antibiotics other than penicillin are used; CSF examination should be performed in these patients at their last follow-up visit. Patients with neurosyphilis should be monitored serologically every 6 months; CSF examinations should be repeated at 6-month intervals until normal. If still abnormal at 2 years, retreatment should be considered. Return of lesions, a fourfold increase in titer, or a titer of 1:8 that does not fall at least fourfold within 12 months necessitates retreatment. Suspected treatment failures, especially with abnormal CSF, should be treated as described for neurosyphilis. However, false-positive serologic results should be ruled out.

Within 2 years, most patients with early syphilis become seronegative. However, if the disease is treated during the late stages, complete seroreversion may not occur. Patients treated with oral doxycycline or erythromycin are less likely to become seronegative.[88] Therapy is considered adequate in patients who never become seronegative as long as the titer decreases fourfold. Although the disease process may be halted in patients with tertiary syphilis, existing damage to the cardiovascular or nervous systems cannot be reversed.

PREGNANCY

CASE 72-8

QUESTION 1: N.W., a 27-year-old woman in her 19th week of gestation, has a positive VDRL and FTA-ABS. How should N.W. be managed? How would management be altered in the face of penicillin allergy?

Although pregnancy may be associated with false-positive nontreponemal tests,[74] the presence of both a positive treponemal test (e.g., FTA-ABS) and a nontreponemal test (e.g., RPR) virtually excludes a false-positive reaction.[80] The next step is to determine whether N.W. already has been treated adequately. If she has previously received adequate treatment and follow-up and shows no evidence of persistence or recurrence of syphilis, then she requires no further therapy. Pregnancy has no known effect on the clinical course of syphilis.[89] However, her infant should be observed carefully. If N.W. has not been treated previously for syphilis, then she should be treated with penicillin in the same doses recommended for nonpregnant women; some experts recommend a second dose 1 week later of 2.4 million-units of benzathine penicillin.[2]

The goal of therapy should be to treat the mother with syphilis as soon as possible. Syphilis transmission can occur transplacentally as early as 9 to 10 weeks' gestation via direct contact with lesions in the birth canal.[89],[90] If the mother is left untreated, 70% to 100% of fetuses born to mothers with primary or 40% with secondary syphilis may be aborted, stillborn, or born with congenital syphilis (see Case 72-8, Question 3).[91],[92]

There is no completely satisfactory alternative for the pregnant woman with an accelerated allergic reaction to penicillin. Tetracycline, as well as doxycycline, should be avoided during pregnancy, especially during the second or third trimester, because of tetracycline's known effects on the fetus (tooth staining and inhibition of bone growth).[93] Erythromycin has been used to treat pregnant patients with syphilis; however, the transplacental transfer rate of erythromycin is inadequate,[94] potentially explaining the increased rate of aborted or stillborn infants in erythromycin-treated patients. Erythromycin and azithromycin are not recommended as alternative therapy for syphilis during pregnancy.[2] A woman with a history of allergy to penicillin should be skin tested; if allergy is confirmed, she should be desensitized and treated with penicillin.[2] It is possible that the newer cephalosporins may ultimately prove to be acceptable alternatives to penicillin G in the pregnant woman with syphilis, who is allergic to penicillin, but there is sufficient evidence for the CDC to recommend their use. Adequate treatment with penicillin can prevent up to 98% of fetal infections.[95],[96] Serologic titers, at a minimum should be followed up at 28 to 32 weeks' gestation and at delivery. Monthly serologic titers may be considered in women at high risk for reinfection or those in geographical areas of high syphilis rates; thereafter, she should be followed up as any other patient with syphilis.[2]

JARISCH–HERXHEIMER REACTION

CASE 72-8, QUESTION 2: N.W. was treated with an IM injection of 2.4 million-units of benzathine penicillin G. Six hours later, she complained of diffuse myalgias, chills, headache, and an exacerbation of her rash. She was tachypneic, but normotensive. What is this reaction? How should N.W. be managed?

N.W. has developed the Jarisch–Herxheimer reaction (JHR), a usually benign, self-limited complication of antitreponemal antibiotic therapy that develops within hours after treatment of early syphilis.[2] The cause of JHR is not well understood, but it is probably related to the release of cytokines.[97] Clinical manifestations include fever, chills, myalgias, headache, tachycardia, and hypotension. The pathogenesis of the syndrome is uncertain, but the reaction should not be interpreted as an allergic reaction to penicillin. It typically begins within the first 24 hours after antibiotic administration and normally subsides spontaneously, generally subsiding even while antibiotics are continued.[2],[98] Notably, JHR can occur after administration of many antimicrobials and is not exclusive to penicillins, nor is it exclusive to syphilis treatment, occurring in other spirochetal diseases, such as Lyme disease and relapsing fever.[99] Usually self-limiting in nonpregnant patients, the primary risk of this reaction in pregnant women is miscarriage, premature labor, or fetal distress.[2],[100] Pregnant women should seek medical attention if contractions or a change in fetal movements are noted. Close monitoring of JHR should be observed for patients with ophthalmic or neurologic syphilis. For these patients, prednisolone 10 to 20 mg 3 times a day for 3 days given 24 hours before syphilis treatment may prevent fever, but it will not control local inflammation.[86] Tumor necrosis factor-α has been demonstrated to have some success in the prevention of JHR in spirochete disease.[101] Although there is no proven effective preventive therapy, some experts still recommend antipyretics, hydration, and patient education; antibiotic therapy should not be discontinued.

NEONATAL SYPHILIS

CASE 72-8, QUESTION 3: How should N.W.'s baby be treated if a diagnosis of congenital syphilis is confirmed?

Infants born to mothers who have been treated for syphilis during pregnancy should be carefully examined at birth with a quantitative nontreponemal serologic test. If tests are reactive, the infant should be followed and have serologic testing every 2 to 3 months until nontreponemal tests are nonreactive.[2] Newborn serology is difficult to interpret because of transplacental transfer of nontreponemal and treponemal immunoglobulin G to the infant. Treatment decisions are largely based on evidence of syphilis in the mother, adequacy of maternal treatment, comparison of maternal and neonatal nontreponemal serology, and/or presence of clinical or laboratory evidence of syphilis in the neonate. In addition, infants should be treated at birth, even if they are asymptomatic, when maternal treatment is unknown or inadequate, or when infant follow-up cannot be guaranteed. In most cases, a CSF examination should be performed before treatment is begun to rule out neurosyphilis.

CHANCROID

Chancroid or soft chancre is a painful genital ulcer disease that is often associated with tender inguinal adenopathy. It is caused by Haemophilus ducreyi, a gram-negative bacillus. Chancroid is endemic in developing countries, but its incidence in the United States has steadily declined. In 2013, 10 cases of chancroid were reported in the United States, down from 28 cases in 2009.[4] Chancroid and other genital ulcers have also been implicated in the acquisition and transmission of HIV.

Signs and Symptoms

CASE 72-9

QUESTION 1: T.G., a 31-year-old uncircumcised sexually active male, presents to the STD clinic with complaints of tender lesions on the penis and inguinal regions. He noticed the penile lesions on the external surface of the prepuce (foreskin) 2 days before his visit. The lesions were sharply demarcated but were not indurated; the base of the penile ulcer was covered by a yellow–gray purulent exudate. Right inguinal adenitis was present and extremely painful on palpation. A dark-field examination of the purulent exudate was negative. Gram stain revealed a mixture of gram-positive and gram-negative flora. T.G. claims to have an allergy to penicillin, but no other drug allergies are reported. What is the natural course of chancroid? Does T.G. have signs or symptoms consistent with chancroid? What diagnostic procedures are necessary?

Uncircumcised men, as well as circumcised men, may have an increased risk of chancroid infection and may not respond to therapy. In fact, evidence suggests circumcision is protective against nearly all STDs, including HIV, as well as protecting women against T. vaginalis and BV.[2] A painful genital ulcer appears 3 to 10 days after exposure and begins as a tender, red papule that becomes pustular and ulcerates within 2 days. Chancroid can be suspected if all of the following criteria are met: (1) one or more painful genital ulcers present, (2) regional lymphadenopathy, (3) no evidence of T. pallidum by dark-field examination, and (4) a negative HSV PCR test or HSV culture. As illustrated by T.G., the ulcer may be covered by a grayish or yellow exudate. A Gram stain can be misleading because of the polymicrobic nature of the ulcer and culture and because isolation of H. ducreyi is difficult, requiring specialized specimen collection and growth media.[2]

Treatment

CASE 72-9, QUESTION 2: How should T.G.'s chancroid be treated?

Most strains of H. ducreyi produce a TEM-type β-lactamase, and many strains are resistant to the antimicrobials that traditionally were used to treat chancroid, such as sulfonamides and tetracycline.[102],[103] Currently recommended CDC treatment regimens include azithromycin 1 g PO for 1 dose, ceftriaxone 250 mg IM once, ciprofloxacin 500 mg PO twice a day for 3 days, or erythromycin base 500 mg PO 3 times a day for 7 days. Ciprofloxacin is contraindicated in pregnant and lactating women. Because T.G. has a history of penicillin hypersensitivity, azithromycin as a single oral dose is a preferred treatment regimen. Treatment may not be as effective for patients who are coinfected with HIV or who are uncircumcised; therefore, HIV testing should occur at the time of chancroid diagnosis and if negative, should be repeated 3 months after the diagnosis. Follow-up should occur 3 to 7 days after treatment is initiated. Depending on the size of the ulcer, the time required until complete recovery will vary; larger ulcers may require longer than 2 weeks. Because T.G. is also sexually active, his sexual partner should be evaluated and treated if they had contact during the 10 days prior to the onset of symptoms.[2]

VAGINITIS

Approximately 10 million physician office visits are made annually in the United States for women seeking evaluation and treatment of vaginitis.[104] The term vaginitis refers to such nonspecific vaginal symptoms as itching, burning, irritation, and abnormal discharge that may be caused by infection or other medical conditions. The most common vaginal infections are BV (22%–50% of cases), vulvovaginal candidiasis (VVC; 17%–39% of cases), and trichomoniasis (4%–35% of cases). However, approximately 30% of cases of vaginitis remain undiagnosed.[105]

Bacterial Vaginosis

Bacterial vaginosis (BV) is the most common genital tract infection amongst reproductive aged women.[106] While the exact prevalence of BV varies, one estimate places it at 29.2%. In addition, many sexually active women are infected with G. vaginalis, yet as much as 84% are asymptomatic.[107] During an episode of BV, the normal vaginal lactobacillus flora is replaced by Mobiluncus species, Prevotella species, Ureaplasma species, Mycoplasma species, and increased numbers of G. vaginalis and is associated with an increased, malodorous vaginal discharge.[2]

The evidence for definitive risk factors in BV is inconclusive. Multiple sexual partners, a new sexual partner, douching, lack of condom use, and decreased concentrations of vaginal lactobacilli have been associated with BV. Non-sexually active women are rarely affected.[2] In addition, studies among women who generally have sex with other women show evidence for sexual transmission.[108] The routine treatment of male sexual partners is not recommended because a woman's response to therapy or her likelihood of relapse or recurrence is not impacted by treatment of her sexual partner(s).[2]

SIGNS, SYMPTOMS, AND DIAGNOSIS

CASE 72-10

QUESTION 1: H.H. is a 24-year-old, sexually active woman with a 1-week history of moderate vaginal discharge that has a "fishy" odor, most notable after coitus. She has no complaints of vaginal pruritus or burning. On examination, the discharge appears thin, white, homogeneous, and notably malodorous. A wet mount of the vaginal secretion revealed few leukocytes and numerous "clue cells." The vaginal pH was 4.8, and a characteristic fishy odor was noted when the discharge was mixed with 10% potassium hydroxide (KOH). Does H.H. have signs and symptoms consistent with BV? What diagnostic tests are required?

H.H.'s signs and symptoms are typical of BV. The clinical diagnosis can be confirmed by a vaginal Gram stain that shows overgrowth of the vagina with G. vaginalis and other organisms as noted earlier. A 10% KOH solution mixed with the vaginal secretions yields a transient fishy odor because of the increased production of biogenic diamines (positive amine test). A wet preparation of the specimen reveals "clue cells" (exfoliated vaginal epithelial cells sometimes with adherent coccobacillary pathogens), vaginal pH greater than 4.5, and the characteristic KOH "whiff" test.[2],[109] If there are many white cells, other infections (e.g., T. vaginalis) should be suspected. Self-diagnosis is correct only about 3% to 4% of the time because most women attribute symptoms to poor hygiene.[110]

TREATMENT

CASE 72-10, QUESTION 2: How should H.H. be treated?

Nonpregnant women with symptomatic disease require treatment. CDC-recommended regimens include oral metronidazole 500 mg twice a day for 7 days, metronidazole gel 0.75% intravaginally daily for 5 days, or clindamycin cream 2% intravaginally at bedtime for 7 days.[2] The FDA has approved metronidazole extended release 750 mg once daily for 7 days and a single dose of clindamycin intravaginal cream for the treatment of BV; however, limited data have been published comparing these regimens to established therapies. Alternatively, the CDC recommends either tinidazole 2 g PO every day for 2 days, tinidazole 1 g PO every day for 5 days, clindamycin 300 mg PO 2 times a day for 7 days, or clindamycin ovules 100 mg intravaginally once at bedtime for 3 days.[2] Patients should be instructed to avoid consuming alcohol during treatment with metronidazole and for 72 hours afterward to avoid disulfiram-like reactions. Additionally, clindamycin cream is oil based and may weaken latex condoms or diaphragms. Alternative products include probiotics which have been evaluated in non-pregnant women and have shown to improve cure rates and reduce the reoccurrence of BV, although more studies are needed to establish their role in treatment.[111],[112]

BV has been associated with preterm labor and premature delivery and treatment is recommended for all symptomatic women. The CDC recommends metronidazole 250 mg PO 3 times daily for 7 days or 500 mg PO twice a day for 7 days, or clindamycin 300 mg PO twice daily for 7 days. Teratogenic data suggest that metronidazole is not harmful to the fetus. More recent data suggest that the use of intravaginal clindamycin cream is also safe to use for pregnant women.[2]

Vulvovaginal Candidiasis

Candida albicans is the causative organism of VVC in 80% to 92% of cases, with Candida glabrata and Candida tropicalis accounting for most of the remaining cases.[2],[12],[113],[114] The latter organisms have been identified increasingly as the causative agents of VVC during the past two decades. Approximately 75% of women will experience at least one episode of VVC during their reproductive years and 40% to 45% will have two or more episodes within their lifetime.[105] Less than 5% of women who have VVC have recurrent candidal episodes (defined as four or more episodes of VVC in 1

---

year). Vulvovaginal candidiasis is not usually described as an STD because celibate women may also experience it; however, the incidence of VVC increases when women become sexually active.[114] Because of this, VVC is often diagnosed during evaluation for a suspected STD when women present with vaginal symptoms.

ASSESSING SELF-TREATMENT

CASE 72-11

QUESTION 1: L.L., a 23-year-old woman, purchases a nonprescription antifungal agent to relieve vaginal symptoms that she believes are caused by a vaginal yeast infection. L.L. asks the pharmacist for assistance in the selection of an antifungal agent. What information should be obtained from L.L. before a medication is recommended?

The pharmacist should ask L.L. if this is her first episode of vaginitis or whether she has experienced similar symptoms previously that have been diagnosed as a vaginal yeast infection and treated by a physician. The nonprescription antifungal agents are indicated for the treatment of VVC in women who previously were diagnosed and treated by their physician. Additional questions that should be asked by the pharmacist include current symptoms, whether they are pregnant or not, other current medical conditions or medications, and allergies. Patients should be referred to a physician if any of the following are present: first episode of VVC, has had more than three episodes of VVC within the past 12 months, last episode was less than 2 months ago, is pregnant, is younger than 12, fever, lower abdominal, back, or shoulder pain, severe symptoms, or has a malodorous vaginal discharge.[115]

SIGNS AND SYMPTOMS

CASE 72-11, QUESTION 2: L.L. has experienced two episodes of vaginal yeast infections, with the most recent case occurring approximately 1 year ago. On both occasions she was diagnosed as having VVC by her physician and responded to antifungal therapy. L.L. currently describes vaginal and vulvar itching, vaginal soreness, and vulvar burning accompanied by a thick, white vaginal discharge that has the consistency of cottage cheese. She has been unable to have sexual intercourse because of pain. These symptoms are similar to those she experienced with her previous vaginal yeast infections. L.L. has no underlying major health problems. Her current medications include oral tetracycline for acne and Ortho Tri-Cyclen for birth control. She has regular menstrual cycles and her last menstrual period ended 4 days ago. What clinical manifestations does L.L. exhibit that are consistent with VVC? What are the other common manifestations?

L.L. exhibits signs and symptoms associated with VVC (i.e., vulvar and vaginal pruritus, vaginal soreness, vulvar burning, dyspareunia, and a thick, white vaginal discharge that appears to be curd-like). Women may also have vaginal discharge which is usually described as nonodorous, highly viscous, and white in color that may vary in consistency from curd-like to watery. Vulvar erythema may also be present.[104]

DIFFERENTIAL DIAGNOSIS

CASE 72-11, QUESTION 3: How can VVC be differentiated from other vaginal infections?

VVC should be differentiated from other vaginal infections because a nonprescription antifungal agent could delay the appropriate treatment of other vaginal infections. The physical appearance of the vaginal discharge may be useful in predicting VVC if it is a viscous, nonodorous, white, curd-like discharge and the patient has a normal vaginal pH (pH <4.5). The quantity of the discharge may be scanty to profuse. Some women with VVC exhibit only vaginal erythema with minimal discharge or an increased amount of normal vaginal secretion. Table 72-5 characterizes the vaginal discharges associated with VVC, BV, and trichomoniasis. The vaginal discharge from a woman with signs and symptoms of VVC should be examined for the microscopic presence of Candida using a wet-mount preparation with 10% KOH or a Gram stain of the vaginal discharge. The use of KOH improves the visualization of yeast or pseudohyphae that are seen in approximately 70% of women diagnosed with VVC. If the wet mount is negative, the patient's vaginal discharge should be cultured for Candida in an appropriate growth medium. Isolation of Candida without signs and symptoms should not result in treatment, because Candida is part of normal vaginal flora in approximately 10% to 20% of women. It is the proliferation of C. albicans or other yeasts that lead to vulvovaginitis symptoms. Nonprescription home screening tests are also available that measure pH levels within the vaginal epithelium (e.g., Vagisil Screening Kit and Fem-V), which are highly sensitive to pH changes but suffer from low specificity.

Physiologic Vaginal Discharge and Symptomatic Normal pH Vulvovaginitis

CASE 72-11, QUESTION 4: Do women such as L.L., who have an increased vaginal discharge and symptoms consistent with VVC, necessarily have a vaginal infection?

Although the possibility of vaginal infection must be addressed when a woman presents with an increased vaginal discharge with or without symptoms, other conditions are associated with an increased discharge. First, a physiologic vaginal discharge must be distinguished from a pathologic discharge. Physiologic discharges (Table 72-5) characteristically are nonodorous, white or clear, highly viscous or floccular, and acidic (pH ~4.5). Physiologic discharge may also become more profuse at midcycle secondary to increased cervical mucus or vaginal epithelial cells. Other conditions resulting in excessive vaginal discharge include retention of foreign bodies (e.g., tampons) and allergic reactions or contact dermatitis secondary to the use of vaginal spermicidal agents, soaps, deodorants, douches, vaginal lubricants, and condoms. Episodes of vulvovaginitis-like symptoms can be associated with frequent use of hot tubs, Jacuzzi baths, or swimming pools that contain chemically treated water with high levels of chlorine.[116]

Table 72-5

Characteristics of Vaginal Discharge

Characteristics	Normal	Candidiasis	Trichomoniasis	Bacterial Vaginosis
Color	White or clear	White	Yellow–green	White to gray
Odor	Nonodorous	Nonodorous	Malodorous	Fishy smell
Consistency	Floccular	Floccular	Homogeneous	Homogeneous
Viscosity	High	High	Low	Low
pH	<4.5	4–4.5	5–6.0	>4.5
Other characteristics		Thick, curd-like	Frothy	Thin

RISK FACTORS FOR VULVOVAGINAL CANDIDIASIS

CASE 72-11, QUESTION 5: What specific groups of women are most susceptible to VVC? Does L.L. fit into any group at high risk for VVC?

C. albicans colonization and symptomatic VVC increases during pregnancy and with use of high-estrogen containing oral contraceptives. Estrogens increase binding affinity of vaginal epithelial cells to C. albicans.[117] Women with high glycogen concentrations (e.g., uncontrolled or poorly controlled diabetes mellitus); women with depressed cell-mediated immunity secondary to disease (e.g., cancer, HIV infection); and women receiving broad-spectrum antibiotics or immunosuppressive drugs (e.g., cytotoxic agents, corticosteroids) are also at risk for VVC.[115] Individual cases of VVC, although not related to intercourse, may be related to orogenital sex.

L.L. is taking tetracycline, which may increase her risk for VVC. Antibacterials increase the risk for C. albicans overgrowth by suppressing the normal vaginal flora (e.g., lactobacilli), which normally protect against C. albicans. L.L. is also taking a low-estrogen–containing oral contraceptive; however, low-dose oral contraceptives have not been consistently associated with an increased risk of VVC. The use of diaphragms, vaginal sponges, and IUDs may also be risk factors for VVC.[115]

Stress-induced VVC and an increased incidence of VVC before menstruation have been described.[117] The cause of both is currently unknown. Although various dietary factors have been postulated as a cause of vaginal yeast overgrowth, the role of diet in the development of VVC remains inconclusive.[117]

TREATMENT OF VULVOVAGINAL CANDIDIASIS

Vaginally Administered Azoles

CASE 72-11, QUESTION 6: What vaginally administered therapy is effective for L.L.'s VVC?

L.L. is an appropriate candidate for nonprescription therapy (Table 72-6) because she had previous vaginal yeast infections with symptoms similar to those she currently is experiencing and her VVC is uncomplicated (defined as sporadic disease with mild-to-moderate symptoms in an immunocompetent host). When a patient's VVC appears complicated (defined as a recurrent infection, severe symptoms, non–C. albicans infection, presence of uncontrolled diabetes, immunosuppression, and/or pregnancy), she should be referred to her medical practitioner.[2] L.L. should respond well to short-term topical azole therapy. In addition, L.L. should ask her physician whether continuation of antibiotics is truly needed. If L.L. had been evaluated by her physician, a prescription for single-dose oral fluconazole or 3-day intravaginal therapy might have been an option.

The available azole antifungals are equally effective in treating VVC with cure rates between 80% to 90% when a full course of therapy is completed.[2,12,118] All the azole antifungal products listed in Table 72-6 are superior to nystatin, which is no longer recommended by the CDC.[2] The medication used to treat L.L.'s VVC should be selected based on response or failure to previous therapy, convenience, ease of use, length of therapy, dosage form, and cost. L.L. should select a non–oil-based product if a latex condom or a diaphragm is used as a form of contraception (Table 72-6).

Other Treatments for ACUTE Vulvovaginal Candidiasis

Oral lactobacillus and lactobacillus-containing yogurt are advocated for the treatment of VVC; however, evidence in support of this treatment is inconclusive.[119] Boric acid 600 mg capsules inserted in the vagina at bedtime for 14 days is effective for the treatment of recurrent VVC with eradication rates of 70%, but vaginal burning and irritation are common side effects and is poisonous if inadvertently ingested.[2,12,119] Gentian violet preparations also have limited use in the treatment of candidiasis because they stain clothing and bed linens and cause local irritation and edema.

Oral Azoles

CASE 72-11, QUESTION 7: How effective are orally administered azoles in the treatment of an acute VVC infection such as the one L.L. is experiencing?

Fluconazole is the only oral antifungal agent currently recommended by the CDC for the treatment of acute VVC. A single 150 mg oral dose of fluconazole is as effective as 3- to 6-day regimen of intravaginal clotrimazole.[120,121] Although some women may prefer an orally administered drug to one that is administered intravaginally, their use for mild-to-moderate VVC is of some concern because of the possibility for systemic adverse effects and drug–drug interactions.

Adverse Effects Associated with Azoles

CASE 72-11, QUESTION 8: What adverse effects might L.L. experience from intravaginally or orally administered azoles?

When used intravaginally, azoles are associated with dose-dependent adverse reactions similar to symptoms women report from VVC. Thus, it can be difficult to differentiate disease symptoms from adverse drug reactions. If the vaginal symptoms worsen after therapy is started, the patient should contact her health care provider. In addition, if symptoms have not improved within 3 days after initiation of therapy or continue past 7 days, the patient should contact her physician to rule out more severe disease or treatment of the wrong disease.[117] Topical azole therapy has been associated with a variety of adverse drug reactions, including headaches, allergic contact dermatitis, vulvovaginal pruritus and irritation, dyspareunia, and general burning, soreness, and genital pain. Oral fluconazole has been associated with headaches, nausea, abdominal pain, diarrhea, dyspepsia, dizziness, taste perversion, angioedema, and rare cases of anaphylactic reactions. In addition, intravaginal miconazole has been reported to interact with warfarin, increasing the risk of bleeding and bruising.[122]

PATIENT COUNSELING

CASE 72-11, QUESTION 9: How should L.L. be counseled about the use of a nonprescription vaginal antifungal product?

Table 72-6

Recommended Regimens for the Treatment of Candida Vulvovaginitis

Drug	Availability	Trade Names	Dosing Regimens
Nonprescription Products			
Butoconazole	2% vaginal cream[a]	Femstat 3	Nonpregnant women: administer 1 applicatorful intravaginally QHS for 3 consecutive days
			Pregnant women during second and third trimesters: administer 1 applicatorful intravaginally QHS for 7 consecutive days
Clotrimazole	1% vaginal cream[a]	Gyne-Lotrimin 7; Mycelex-7; Clotrimazole 7; various generics	Administer 1 applicatorful intravaginally QHS for 7 to 14 consecutive days
	2% vaginal cream[a]	Gyne-Lotrimin 3; various generics	Administer 1 applicatorful intravaginally QHS for 3 consecutive days
Miconazole	2% cream[a]	Monistat 7; Femizol-M; various generics	Administer 1 applicatorful intravaginally QHS for 7 consecutive days
	4% cream[a]	Monistat 3; various generics	Administer 1 applicatorful intravaginally QHS for 3 consecutive days
	100-mg vaginal suppositories[a]	Monistat 7	Insert 1 suppository intravaginally QHS for 7 consecutive days
	200-mg vaginal suppositories[a]	Monistat 3	Insert 1 suppository intravaginally QHS for 3 consecutive days
	1,200-mg vaginal suppositories[a]	Monistat 1 daytime Ovule	Insert 1 suppository intravaginally QHS for 1 dose only
Tioconazole	6.5% vaginal ointment	Vagistat-1	Administer 1 applicatorful intravaginally at QHS for 1 dose only
Prescription Products			

Butoconazole	2% vaginal cream[a]	Gynazole 1	Nonpregnant women: administer 1 applicatorful QHS for 1 dose only
Fluconazole	150-mg oral tablet	Diflucan	Take 1 tablet PO for 1 dose only
Terconazole	0.4% vaginal cream[a]	Terazol 7	Administer 1 applicatorful intravaginally QHS for 7 consecutive days
	0.8% vaginal cream[a]	Terazol 3	Administer 1 applicatorful intravaginally QHS for 3 consecutive days
	80-mg vaginal suppositories[a]	Terazol 3	Insert 1 suppository intravaginally QHS for 3 consecutive days

[a] The CDC states that the use of vaginally administered oil-based preparations may weaken latex products such as condoms and diaphragms.

QHS, at bed time.

Adapted from Workowski KA, Berman S; Centers for Disease Control and Prevention (CDC). Sexually transmitted diseases treatment guidelines, 2013. MMWR Recomm Rep. 2015;64(RR-03):1–137.

The details of intravaginal administration should be reviewed with L.L., including instructions on how to clean the applicator. To minimize leakage and annoyance, L.L. should apply the product at bedtime to increase retention in the vagina. She should be advised that the nonprescription vaginal antifungal creams and suppositories are oil based and thus may weaken condoms or diaphragms, thereby reducing their effectiveness.

L.L. should be informed about the importance of completing a full course of therapy even if her symptoms subside beforehand and to continue her antifungal treatment through her menstrual period should it occur. In addition, L.L. should be instructed to see her physician if her symptoms persist, if she experiences symptoms that signal a more serious problem (e.g., abdominal pain, fever, a foul-smelling or bloody vaginal discharge), and/or if another yeast infection occurs within 2 months.

L.L. also should be advised to avoid wearing tight-fitting, unventilated underwear (e.g., nylon panties or panty hose) and tight-fitting jeans because a warm, moist environment can facilitate fungal growth. However, a study addressing risk factors for VVC found no relation between type of underwear and the incidence of VVC.[123] In fact, many risk factors for VVC are not consistently associated with this infection.[115] L.L. also could be alerted to the possible relation between candidiasis and swimming in a heavily chlorinated pool or frequent use of a Jacuzzi or hot tub.

Complicated Vulvovaginal Candidiasis

CASE 72-11, QUESTION 10: How would management of L.L.'s VVC differ if she had poorly controlled diabetes?

VVC in a woman with uncontrolled diabetes is usually considered to be complicated VVC. A diagnosis of complicated VVC is also warranted when the VVC is severe, recurrent (as defined), caused by non–C. albicans species or when VVC occurs in an immunosuppressed, debilitated, or pregnant woman. The treatment of complicated VVC varies depending on the underlying reason for the complication. Severe VVC (e.g., extensive vulvar erythema, edema, excoriation, and fissures) may be treated with either a 7- to 14-day course of topical azoles or two oral doses of fluconazole 150 mg given 72 hours apart. Infection with non–C. albicans species should be treated with a 7- to 14-day course of an oral or intravaginal azole; however, the optimal treatment is unknown. Oral fluconazole has poor activity against non–C. albicans species and should not be used. Boric acid 600 mg capsules administered intravaginally once daily for 14 days can also be used, which has shown eradication rates of 70%.[2]

Recurrent Vulvovaginal Candidiasis

CASE 72-11, QUESTION 11: L.L. experiences another case of VVC 1 month later. Does she have recurrent VVC? How should she be treated?

Most women have only occasional episodes of VVC, but approximately 5% experience recurrent VVC infections defined as four or more episodes per year. To determine whether L.L. has recurrent VVC, a diagnosis of Candida needs to be confirmed by vaginal cultures. Then, underlying risk factors for VVC, such as uncontrolled diabetes mellitus, consumption of excess sugars, IUD placement, and use of antibiotics, must be ruled out.[124] Based on the timing of L.L.'s episodes and the absence of risk factors, L.L. does not meet the definition for recurrent VVC. If a patient meets the criteria for recurrent VVC, an underlying cause of the problem may not be determined. In addition, the role of sexual transmission is not currently well understood.[114] In most patients, the pathogenesis of recurrent VVC cannot be determined.

Treatment of recurrent C. albicans vulvovaginitis should include a prolonged (7–14-day) course of topical therapy or a three-dose regimen of oral fluconazole (100, 150, or 200 mg) administered every 3 days. A 6-month maintenance regimen should be initiated after remission has been achieved (Table 72-7). Despite the efficacy of these regimens, discontinuation of therapy after 6 months can result in relapse in 30% to 50% of women.[2] Azole-resistant strains of C. albicans are rare; therefore, culture and sensitivity testing is not usually performed to help guide treatment before initiation.

Table 72-7

Maintenance Regimens for Recurrent Vulvovaginal Candidiasis

	Dose	**Frequency**
Topical agents		
Clotrimazole	200 mg	Intermittently
Clotrimazole vaginal suppositories	500 mg	Intermittently
Oral agents		
Fluconazole tablets	100, 150, or 200 mg	Weekly for 6 months

[a] Given as examples only, CDC does not indicate a preferred regimen.

Adapted from Workowski KA, Bolan GA; Centers for Disease Control and Prevention (CDC). Sexually transmitted diseases treatment guidelines, 2015. 2015;64(RR-03):1–137.

Vulvovaginal Candidiasis During Pregnancy

CASE 72-11, QUESTION 12: What teratogenic risks are associated with the use of azole preparations?

Vaginal colonization with Candida and symptomatic VVC are common during pregnancy.[125] Asymptomatic colonization is not associated with increased maternal or fetal risks and need not be treated.[126] However, symptomatic VVC should be treated. Although doses of oral fluconazole used to treat VVC have not been associated with increased fetal defects, higher doses may be teratogenic. Therefore, topical antifungal agents are preferred for treatment of VVC in pregnant women. The CDC currently recommends a 7-day course of topical antifungal therapy for VVC during pregnancy; however, a 3-day regimen with appropriate follow-up to assess efficacy has been shown to be effective in mild-to-moderate cases. Clotrimazole is also classified as a category B drug for fetal risk, and the remaining vaginally administered azoles are designated as category C.[126]

Trichomoniasis

SIGNS AND SYMPTOMS

CASE 72-12

QUESTION 1: N.B. is a 31-year-old woman with a recent history of diffuse vaginal discharge and irritation. A wet-mount examination of vaginal secretions revealed numerous trichomonads. Examination confirms the presence of an increased, yellow–green vaginal discharge. What subjective and objective clinical data support a diagnosis of trichomoniasis?

Trichomoniasis is the most prevalent nonviral STD caused by the protozoan T. vaginalis.[2] The overall prevalence is estimated at 3.1% with the highest prevalence among African Americans at 13.3%. Trichomoniasis in women is asymptomatic or with minimal symptoms about 70% to 85% of the time. In men, T. vaginalis presumably infects the urethra, although the site of infection (urethra vs. prostate) is uncertain. Classic symptoms of trichomoniasis in women include a diffuse, yellow–

green discharge with pruritus, dysuria, and a “strawberry” cervix (cervical microhemorrhages). The latter are typically seen only in 2% to 25% of cases.[127] In almost all cases of trichomoniasis, a vaginal pH greater than 5 is observed.[128] The Papanicolaou smear is associated with a 48.4% error in diagnosis when used alone.[127] Direct microscopic observation of trichomoniasis using a wet mount is inexpensive and yields a high specificity, but it has a low sensitivity.[129] Other testing options include culturing, rapid antigen tests, and NAATs.[130]

TREATMENT

Metronidazole and Tinidazole

CASE 72-12, QUESTION 2: How should N.B.’s trichomoniasis be treated?

The only class of drugs that is effective for the treatment of trichomoniasis is the nitroimidazoles. In the United States, metronidazole and tinidazole are the only available nitroimidazoles and both are CDC-recommended first-line agents given as a single 2 g oral dose. In addition, sexual partners should be simultaneously treated to prevent reinfection. Metronidazole cure rates are reported to be 84% to 98%, whereas tinidazole cure rates are reported to be 92% to 100%; concurrently treating sexual partners

---

might increase these rates. Tinidazole offers other advantages, such as higher serum and genitourinary levels, a longer half-life, and fewer gastrointestinal adverse reactions.[2]

Approximately 4% to 10% of T. vaginalis isolates exhibit a low-level resistance to metronidazole therapy and 1% to tinidazole therapy; however, higher-level resistance appears to be rare.[2],[131] If metronidazole 2 g PO for one dose fails and reinfection is excluded, metronidazole 500 mg PO twice daily for 7 days can be used. However, if this regimen fails either metronidazole or tinidazole 2 g PO as a single dose for 7 days should be used. In the case of allergy to nitroimidazole compounds, patients should be desensitized to metronidazole and subsequently treated.[2]

Adverse Effects

CASE 72-12, QUESTION 3: N.B. was treated with metronidazole 2 g as a single dose; however, while attending a party, N.B. experienced a severe headache, followed by nausea, sweating, and dizziness. Could N.B.’s symptoms be caused by metronidazole?

Minor side effects associated with metronidazole therapy include nausea, vomiting (especially with single-dose therapy), headache, skin rashes, and alcohol intolerance. The alcohol intolerance may be attributable to a metronidazole-induced inhibition of aldehyde dehydrogenase, which results in the buildup of high serum acetaldehyde levels, although the true risk of this interaction has been debated.[132] According to the manufacturer, patients should be warned about the possibility of nausea, vomiting, flushing, and respiratory distress after alcohol consumption, although reliable evidence is lacking.[123] As a general rule, patients should avoid alcohol ingestion during treatment and for 72 hours after metronidazole or tinidazole therapy. In those patients who cannot otherwise tolerate oral metronidazole or tinidazole, a combination of intravaginal miconazole and metronidazole may be an effective alternative.[133]

PREGNANCY

CASE 72-13

QUESTION 1: S.G., a 31-year-old woman, is in her first trimester of pregnancy and has a history of recurrent trichomoniasis. She now complains of a diffuse, yellow vaginal discharge. The preliminary diagnosis of trichomoniasis is confirmed by a wet-mount examination of vaginal secretions revealing numerous trichomonads. S.G. has read much in the lay press on metronidazole and is concerned about her own safety as well as that of her fetus. Can metronidazole be used for S.G.?

During pregnancy, trichomoniasis is associated with premature rupture of the membranes, preterm delivery, and low birth weight. In one study, rates of preterm delivery appeared to increase in women who received metronidazole, but a definitive causation could not be determined.[134] However, caution should still be exercised if metronidazole must be administered within the first trimester. Metronidazole is mutagenic in facultative bacteria and contains a nitro-reductase enzyme. Long-term, high-dose metronidazole in laboratory mice is associated with the development of pulmonary and hepatic tumors. Midline facial defects have been documented in humans, but two literature reviews indicate that metronidazole is not a teratogen.[135],[136] In contrast, the use of metronidazole in asymptomatic women has not been shown to decrease rates of preterm labor despite eliminating the organism from its host.[137]

Treatment

CASE 72-13, QUESTION 2: How should S.G. be treated?

All symptomatic women should be treated with metronidazole 2 g PO as a single dose. Metronidazole is classified as pregnancy category B. Tinidazole 2 g PO as a single dose could be suggested as an alternative regimen; however, it is classified as pregnancy category C.[2]

GENITAL HERPES

The word herpes is of Greek origin and means "to creep." HSV is a DNA-containing virus that consists of two antigenically distinct serotypes: HSV-1 and HSV-2. The primary cause of herpes labialis (cold sores), herpes keratitis, and herpetic encephalitis is HSV-1. Genital herpes and neonatal herpes primarily are the result of HSV-2 infections. However, up to 50% of all reported cases of primary genital herpes are caused by HSV-1 infections acquired through oral sex.[138],[139]

Etiology

Most people are exposed to HSV-1 early in life with more than half being positive for HSV-1 antibodies before 18 years and more than 90% of the population positive by 70 years of age.[140] The infection is often asymptomatic and generally acquired through primary infection of mucocutaneous surfaces. The initial, primary disease is a gingivostomatitis characterized by vesicles in the oral cavity and occasionally an elevated temperature; life-threatening encephalitis or keratitis may appear during this interval. Usually after primary exposure, HSV-1 enters cells of the trigeminal ganglion, where it may remain latent for the lifetime of the host.[141]

Initial HSV-2 infections usually occur after puberty and coincide with the onset of sexual activity, although transfer to a neonate from an infected mother can occur. After primary infection, the virus enters a state of latency in the sacral dorsal root ganglia in many infected individuals; a high percentage of infected persons may never manifest the disease clinically.[141],[142]

In both HSV-1 and HSV-2 infections, the latent virus can reactivate. Recurrent disease may occur even when circulating antibody and sensitized lymphocytes are present. Clinically, the lesions periodically erupt usually at the same location, and the interval between episodes varies widely between individuals.

Epidemiology

Although herpes was recognized several thousand years ago, genital herpes was not described until the 18th century. The seroprevalence of genital herpes (HSV-2) has remained the same in the United States since 1999—at approximately 16.2% overall in 19- to 49-year olds, but 20.9% in women and 39.2% in non-Hispanic blacks—making it still one of the most common STDs in the United States.[143] In 2013, US physicians saw more than 300,000 new patients presenting with genital herpes simplex and nearly 20% of non-Hispanic white females and more than double that in non-Hispanic black females are already seropositive in the United States.[4]

Demographic characteristics obtained at the University of Washington indicate that the mean number of lifetime sexual partners before acquisition of the disease was 8.8

in women compared with 32.8 in men, with the overall chance of acquiring HSV-2 of 5 per 1,000 sex contacts.[144] The range of time from the last sexual exposure to the onset of disease is 5 to 14 days.[142] Whether causal or not, HSV-2 infection increases the risk of HIV acquisition.[145] Of recent concern, the seroprevalence of HSV-1 in 14- to 19-year olds declined by 23% from 1999 while the rate of HSV-2 remained unchanged, indicating that many young adolescents will not have protective HSV-1 antibodies at sexual debut and HSV-2 prevalence may rise.[146]

Signs and Symptoms

CASE 72-14

QUESTION 1: B.J., a 28-year-old, sexually active man, complains of painful penile lesions and tender inguinal adenopathy. The lesions are vesicular and limited to the scrotum, glands, and shaft of the penis. The onset of the lesions was preceded by a 1-week period of fever, malaise, headache, and itching. Viral culture of the lesions was positive for HSV infection. Describe the typical course and clinical presentation of herpes genitalis in men and women. What subjective and objective clinical data in B.J. are compatible with herpes genitalis?

Most initial episodes of genital herpes, especially in the male, are symptomatic. As illustrated by B.J., the symptoms usually start about 1 week after the initial exposure with prodromal signs of tingling, itching, paresthesia, or genital burning. The prodromal stage, which can last from a few hours to several days, is followed by the appearance of numerous vesicles. The vesicles eventually erupt, resulting in painful genital ulcers. The pain and edema associated with genital herpetic lesions, especially if they are infected secondarily, can be severe enough to result in dysuria and urinary retention. Bilaterally distributed lesions of the external genitalia are characteristic. The lesions usually are limited to the glands, corona prepuce, and shaft of the penis in males and to the vulva and vagina in females. However, lesions can occur on the buttocks, thighs, and urethra.[142] Asymptomatic or mucopurulent cervicitis occurs in about 15% to 20% of women with primary HSV-2 infections.[147] Rectal and perianal HSV-2 infections are more common in MSM and immunocompromised individuals.[148] Symptoms include anorectal pain and discharge, tenesmus, and constipation.

Prior infection with HSV-1 may ameliorate the severity of the first episode of genital herpes, but it does not impact the rate of recurrence.[149] In primary infections, the local symptoms of pain, itching, and urethral or vaginal discharge last from 11 to 14 days, with a complete disappearance of lesions in 3 to 6 weeks.[142,150] The clinical course of primary herpes is presented in Figure 72-7. Most patients have minor symptoms or are asymptomatic and unaware of their disease; they are most infectious within the first year of acquisition of the virus.[151]

Recurrence

CASE 72-14, QUESTION 2: Is B.J.'s infection likely to recur?

Most first episode HSV-2 symptomatic patients experience a recurrence of their initial infection.[2] The rate of recurrent infections varies among individual patients. Approximately 38% experience at least six episodes, and 20% have more than 10 recurrences.[150] Natural infection with HSV-2 induces type-specific immunity against exogenous reinfection, but it does not affect recurrences.[152] The severity of the primary episode and recurrence appear to be influenced by the host's immune status, especially a depressed T-cell response.[142] Recurrent infections usually appear at or near the site of the initial infection, and prodromal symptoms are reported by about 50% of persons with recurrent infection. Men recur more frequently than women. In contrast with primary infections, there are fewer lesions and they are often unilateral.[142] Constitutional symptoms such as lymphadenopathy, fever, and malaise generally are also milder. Recurrent infections are shorter in duration (average, 1 week); local symptoms such as pain and itching last 4 to 5 days and the lesions themselves last 7 to 10 days.[142] Although there is wide variability, patients may have four to five recurrences during the first year, but reactivation frequency can decline by three reactivations per year during the first 2 years.[153],[154] By about 5 years after the initial infection, recurrence rates decrease greatly.[155] Genital infections with HSV-1, however, recur infrequently and decrease by 50% between 1 and 2 years after infection.[156]

Transmission

CASE 72-14, QUESTION 3: B.J. states that this is the first time he has had such lesions and that he has had only one sexual partner for the last 14 months. His sexually active female partner has no history of herpes genitalis or any other STD. The couple is very curious as to how B.J. acquired his infection. How is HSV transmitted?

Transmission of HSV occurs by direct contact with active lesions or from a symptomatic or asymptomatic person shedding virus at a peripheral site, mucosal surface, or secretion.[157] Genital HSV-2 infections usually are acquired through sexual (vaginal or anorectal) intercourse, whereas genital HSV-1 infections are acquired through orogenital sexual practices. Because HSV is inactivated readily by drying and exposure to room temperature, aerosol and fomite spread are unusual means of transmission.[158] Condoms may act as an effective barrier to viral transmission in women, but this method does not offer complete protection for men as women often have perigenital lesions.[159] Evidence suggests that the frequency of correct condom use is directly proportional to protection against acquisition of HSV-2 and that condoms are more likely to be worn when lesions are present.[160],[161]

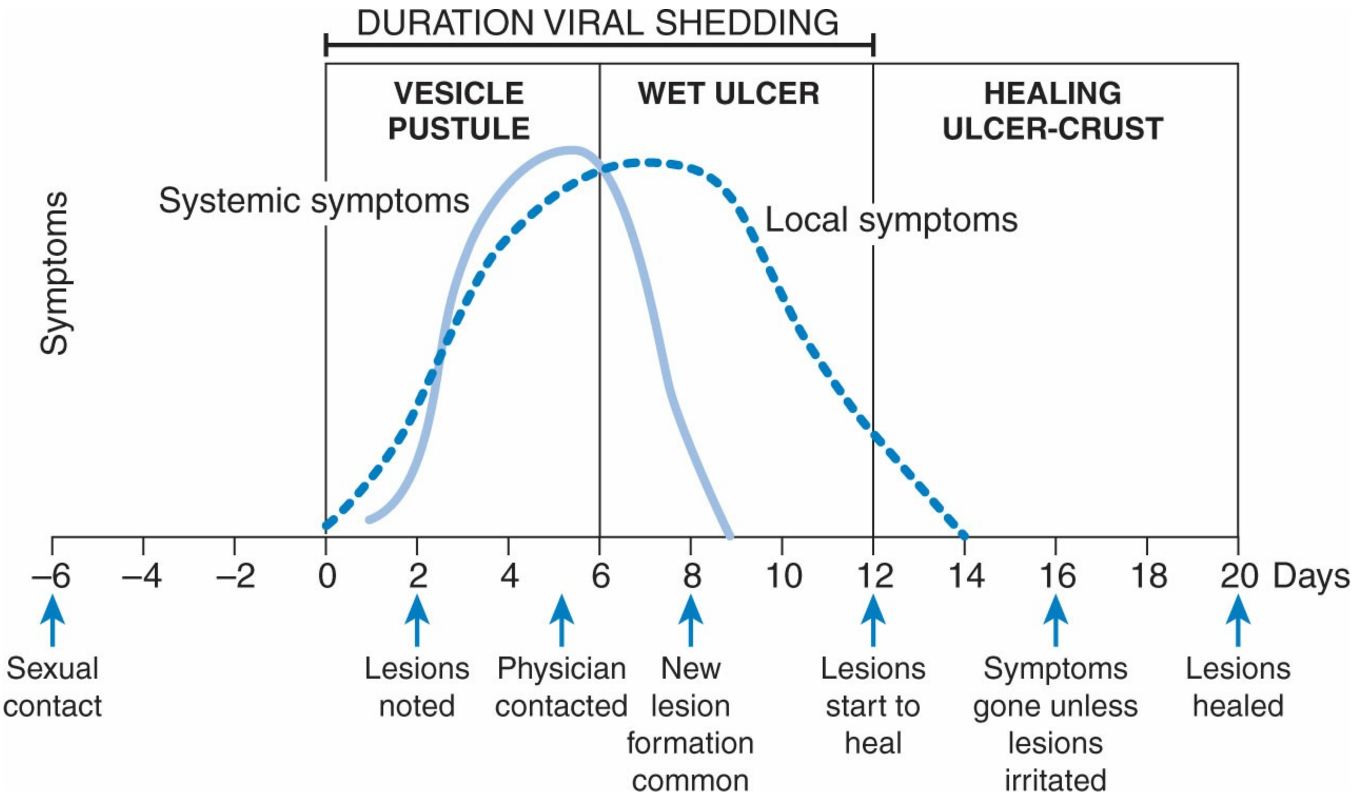

Figure 72-7 The Clinical Time Course of Primary Genital Herpes Infections. (Adapted with permission from Corely L, Wald A. Genital Herpes. In: Holmes K et al., eds. Sexually Transmitted Diseases. 4th ed. New York, NY: McGraw-Hill; 2008:399.).

p. 1528

p. 1529

A patient with genital herpes is contagious only when shedding the virus. The patient begins to shed virus during the prodromal phase, which may be several hours to days before the actual lesions first appear. Patients can, however, be asymptomatically diagnosed by serology and subsequently develop clinical lesions or be symptomatic on diagnosis and have recurrent episodes of clinical lesions. Symptomatic viral shedding occurs twice as often than in asymptomatic HSV-2 seropositive individuals, but subclinical viral shedding (i.e., no lesions present) still occurs approximately 10% of days, regardless of gender.[162] From a public health standpoint, unrecognized subclinical shedding may indicate a greater need for serologic testing to reduce transmission.[163],[164] Lesions are most contagious during the ulcerative phase. The median duration of viral shedding as defined from onset to the last positive culture is about 12 days.[142] The mean time from the onset of vesicles to the appearance of the crust stage (~10.5 days) correlates well with the duration of viral shedding. However, there is considerable overlap between the duration of viral shedding and the duration of crusting. Women require a longer healing time than men, 19.5 and 16.5 days, respectively.[142] The mean duration of viral shedding from the cervix is 11.4 days. Therefore, patients should be advised to refrain from sexual activity until the lesions have completely healed; however, subclinical viral shedding may also transmit HSV-2.

A genital herpes infection may be acquired from an individual who has never had symptomatic genital lesions. States of asymptomatic or subclinical viral shedding occur in the majority of women with recurrent genital herpes as a result of reactivation of latent infection. These recurrent infections can have a primary disease presentation, causing the patient to blame the most proximate sexual partner when in actuality the exposure could have occurred in the distant past.[165] Serologic and virologic typing can be used to determine whether this is a true primary infection. Using sensitive detection techniques, such as PCR, women with recurrent HSV infections shed virus up to 28% of the time, but the relationship between a PCR-positive HSV test and true communicability has yet to be determined.[166] In addition, asymptomatic spread can occur from multiple anatomic genital sites and in a bilateral fashion, even with previous outbreaks of unilateral lesions.[167]

Seropositive HSV patients also should be counseled to practice safer sex, using male or female condoms, at all times, not just during symptomatic episodes.[168]

Diagnostic Tests

CASE 72-14, QUESTION 4: Viral culture was negative for B.J., but HSV-2 point-of-care (POC) serology was positive for both B.J. and his sexual partner. How should these laboratory tests to be interpreted?

The accuracy with which herpes genitalis can be diagnosed without the aid of laboratory tests generally is difficult to achieve, especially if the infection is not symptomatic. Thus, because of the potentially severe psychologic and physiologic ramifications of such a diagnosis, either virologic and/or serologic confirmation of the diagnosis may be obtained.

The laboratory diagnosis of HSV-1 or HSV-2 infection depends on isolation of virus using viral culture, while HSV DNA detection by PCR is more expensive than viral culture and not as widely available or HSV antigen detection using EIA or DFA. Both PCR and EIA can differentiate HSV-1 from HSV-2. Currently, HSV DNA PCR is the most sensitive method for detecting mucocutaneous herpes simplex infection rather than simple viral culture in those with genital ulcers and is the preferred method for CSF samples.[142] Tests that measure serologic response, antibody production, are valuable in documenting primary infection, but they are not very useful in recurrent infections or to determine when the initial infection occurred. It is possible to differentiate between antibodies to HSV-1 and HSV-2 by means of type-specific serologic assay. POC devices using HSV-2—specific antibody testing kits offer ease, reduced time, differentiation between HSV-1 and HSV-2, and high sensitivities and specificities.[12],[169],[170]

Viral culture is more likely to yield false-negative results than other testing methods.[12] A better antigen detection test could have been used, such as an EIA or DFA. The lack of a positive viral culture does not rule out the diagnosis of a primary infection in B.J., especially because the antibody test was positive. The fact that

B.J.'s partner's antibody test was positive without a history of symptomatic disease suggests a distant infection with asymptomatic shedding.

Treatment

CASE 72-14, QUESTION 5: How should B.J.'s lesions be managed? Because the likelihood of recurrence of genital herpes is high, what treatment and prevention measures are recommended currently?

A diagnosis of genital herpes is concerning because there is no cure for the condition. Therapies ranging from antiviral agents and photoinactivation to investigational vaccines have been tried. Currently, only acyclovir (ACV), famciclovir (FCV), and valacyclovir (VCV) are useful in the treatment and prevention of genital herpes.

The ideal anti-HSV agent should (a) prevent infection, (b) shorten the clinical course, (c) prevent the development of latency, (d) prevent recurrence in patients with established latency, (e) decrease transmission of disease, and (f) eradicate established latent infection.[142] To date, no agent has been successful in achieving all of these goals.

All three agents, ACV, FCV, and VCV, are effective for the short-term treatment of some HSV infections. ACV, a nucleoside analog, is a substrate for HSV-specific thymidine kinase. Through a series of phosphorylation steps, ACV is transformed to ACV-triphosphate, a competitive inhibitor of viral DNA polymerase. ACV has potent in vitro activity against both HSV-1 and HSV-2 and is far less active against varicella-zoster and CMV.[171] FCV, a prodrug of penciclovir, has increased oral bioavailability compared with acyclovir. Once converted in the intestine and liver to the active form, penciclovir, it is quickly phosphorylated in HSV in a similar manner as ACV. VCV is the L-valyl ester prodrug of ACV. The oral bioavailability of VCV is also significantly better than ACV, producing plasma levels of ACV comparable to those attained with IV administered ACV, often eliminating the need for parenteral therapy.[172] All three antiviral drugs are equally effective for genital herpes infections.

Intravenous ACV (5 mg/kg/dose every 8 hours) significantly reduced the duration of viral shedding in primary genital herpes, decreasing the duration of signs and symptoms of disease by a mean of 5 days, and the time to healing of lesions by a mean of 6 to 12 days compared with placebo-treated patients.[12],[173] Similar findings have been shown in the immunocompromised patient population.[174] IV and oral ACV or VCV also prevent HSV reactivation in seropositive immunocompromised patients who are undergoing bone marrow transplantation.[175] For patients with HIV, ACV 400 mg PO 3 times daily, FCV 500 mg twice daily, or VCV 500 mg twice daily for 5 to 10 days have been used for recurrent episodes.[2] Currently, IV therapy is recommended only for patients with severe genital or disseminated infections who cannot take oral medication.

Table 72-8

Antiviral Chemotherapy of Genital HSV-2 Infections

	Acyclovir	Valacyclovir	Famciclovir	Duration	Comments
First clinical episode	400 mg PO TID or 200 mg PO 5 per day	1 g PO BID	250 mg PO TID	7–10 days	May extend treatment duration if healing is incomplete
Episodic recurrent infection	400 mg PO TID or 800 mg PO BID or 800 mg PO TID × 2 days	1 g QD or 500 mg PO BID × 3 days	125 mg PO BID or 1,000 mg PO BID × 1 day or 500 mg PO × 1, then 250 mg BID × 2 days	5 days	Most effective if initiated within the first 24 hours of onset of lesions or during the prodrome
Daily suppressive therapy	400 mg PO BID[a]	500 mg PO QD[b] or 1 g PO QD	250 mg PO BID	Daily	Reduces the frequency of genital herpes recurrences by ≥75% among patients who have frequent recurrences (i.e., ≥6 recurrences per year); use should be reevaluated at 1 year
Severe disseminated	5–10 mg/kg IV q8h	Not indicated	Not indicated	Variable	Hospitalize and treat until clinical resolution of symptoms Follow-up IV therapy with PO ACV to complete 10 days
HIV-infected: episodic	400 mg PO TID or 200 mg 5 per day	1 g PO BID[c]	500 mg PO BID	5–10 days	Treat until clinical resolution of lesions
HIV-infected: suppressive	400–800 mg PO BID or TID	500 mg PO BID[d]	500 mg PO BID		

Note: Regimen recommendations derived from 2002 CDC Recommendations.[13]

[a] Safety and efficacy up to 6 years have been documented with the use of acyclovir.

[b] Valacyclovir 500 mg QD seems less effective in patients with >10 episodes per year. Thus, 1 g QD should be used in these patients.

[c] Dosages up to 8 g/day have been used, but an association with a syndrome resembling either hemolytic uremic syndrome or thrombotic thrombocytopenic purpura was observed.

[d] Effective in decreasing both the rate of recurrences and the rate of subclinical shedding among HIV-infected patients.

Topical therapy with ACV ointment (5% in polyethylene glycol) has minimal effect on the duration of viral shedding, symptoms, and lesion healing in first-episode primary genital herpes, and it has no effect on the recurrence rate[175] and is not recommended for primary genital herpes. Penciclovir 1% cream applied every 2 hours while awake is effective for treatment of herpes simplex labialis,[176] but insufficient data exist to recommend its use for genital herpes infections.

Oral antivirals speed the healing and resolution of symptoms of first and recurrent episodes of genital HSV-2 infections.[177] Treatment of primary infection after the first week of infection does change the natural history of recurrent outbreaks; thus, patients should be educated about risk of sexual transmission and prompt recognition of signs and symptoms and the early use of antivirals.[178] The frequency of recurrence decreases with time in most patients. Recurrent episodes of genital HSV-2 infection can be treated with any of the three available oral antivirals (Table 72-8). Rather than having to go into clinic, patients with recurrent infection should have a supply of their antiviral drug with them to allow early initiation of therapy, which may abort or reduce symptoms by 1 to 2 days.[179],[180]

Daily suppressive therapy with ACV, FCV, or VCV reduces the frequency of recurrent episodes up to 70% to 80% among patients with frequent (five to eight episodes per year) genital herpes.[2],[181] Recurrent outbreaks diminish with time; thus, after each year of continuous suppressive therapy, an effort should be made to discuss discontinuing therapy with the patient. The use of suppressive therapy does not completely eliminate viral transmission. However, a randomized, controlled clinical trial of serodiscordant HSV-2—positive couples demonstrated a statistically significant decrease in the rate of transmission to uninfected partners when infected partners took 500 mg/day of VCV.[154] This 8-month study was restricted to heterosexual partners with fewer than 10 recurrences per year. The CDC recommends various dosing regimens for VCV, but the 500-mg once-daily dose appears to be less effective than the 1-g once-daily dose in patients with frequent recurrent episodes (i.e., >10 episodes per year).[2] However, one meta-analysis showed a consistent prophylactic benefit if VCV was dosed at 250 mg twice daily or 500 mg once daily.[182] Immunocompromised patients may require higher doses or more frequent intervals for suppression.[183] Most cases of ACV-resistant HSV occurs in the immunocompromised host; however, the resistance is less than 5%.[184] All ACV-resistant strains are also resistant to VCV, and most are resistant to FCV as well. Foscarnet 40 to 80 mg/kg IV every 8 hours or cidofovir 5 mg/kg once weekly until clinical resolution may be used for severe ACV-resistant genital HSV infections.[2] Cidofovir 1% gel (not commercially available in the United States but has been compounded by pharmacists) applied once daily for 5 days may be an alternative to IV foscarnet, but more studies are needed.[2],[185]

B.J. is not yet a candidate for daily suppressive ACV therapy. A summary of the indications for ACV, FCV, and VCV is outlined in Table 72-8.

ADVERSE EFFECTS

CASE 72-14, QUESTION 6: What adverse effects associated with ACV, FCV, or VCV should be anticipated?

Overall, all forms of ACV, including VCV and FCV, are associated with relatively few adverse reactions largely because of the drugs' affinity for viral thymidine kinase over cellular kinase.

Hematuria and an increase in blood urea nitrogen and serum creatinine may occur, primarily in patients with underlying renal disease or those receiving concomitant nephrotoxic agents. However, this complication is almost entirely associated with the IV route. In addition, severe local reactions are possible with IV administration. In patients with HIV/AIDS, VCV at a dosage of 8 g/day was associated with a hemolytic uremic syndrome or thrombotic thrombocytopenic purpura-like syndrome. However, this complication has not been observed with normal therapeutic doses. As described previously, when given intravenously in high doses or with significant dehydration, ACV crystallizes in the renal collecting tubules of animals, leading to renal insufficiency.[186] ACV should not be rapidly infused or administered at concentrations greater than 10 mg/mL. Dose adjustment is necessary for all three antiviral agents in patients with decreased renal function.

Although neurotoxicity is a rare side effect, case reports of coma and delirium have been reported in patients with renal failure.[187],[188]

Intravenous ACV occasionally has been associated with cutaneous irritation and phlebitis, reversible leukopenia,[189] and transient elevations of liver transaminases. Oral ACV and VCV are relatively safe and do not produce any serious side effects at normal doses. Patients receiving oral ACV, VCV, or FCV may complain of nausea, dizziness, diarrhea, and headaches.

Patient Education and Counseling

CASE 72-14, QUESTION 7: What are the roles for education and counseling in patients with genital herpes? Are other forms of local or symptomatic care useful?

Most genital herpes infections are benign, and lesions heal spontaneously unless the patient is immunocompromised or the lesions have become infected secondarily. The patient should be instructed to keep the involved areas clean and dry. To prevent autoinoculation, the patient should be told not to touch the lesions and to wash his hands immediately afterward if he comes in contact with the lesion. Local anesthetics provide relief from the pain of genital lesions, but they should be avoided if possible because they counteract efforts to keep the lesions dry. Local corticosteroid therapy is contraindicated because it may predispose the patient to secondary infections.

Patient counseling should include the source contact and any future partner. Health care practitioners should attempt to relieve patients' feelings of guilt and anxiety; discussion of long-term consequences should take place after the acute symptoms of the infection have resolved.

For individuals with frequent recurrences, efforts should be made to identify and avoid stimulatory factors such as sunlight, trauma, or emotional stress. The limitations of therapy and the decreased severity and frequency of recurrences with time should be explained to the patient. The periods of infectivity and the need to avoid sexual activity even when lesions are not present should be emphasized, indicating the need for continuous barrier protection. Women with herpes genitalis should be scheduled for routine Pap smears and should be instructed to discuss their HSV with their physicians if they become pregnant.

Currently, there is no completely effective way to prevent the transmission of HSV-2 infection. Barrier forms of contraception, in particular condoms, may reduce the transmission of HSV, but this may be limited only to male-to-female transmission owing to the large area that herpes lesions may occupy on the woman.[159] However, greater use of condoms by men can increase protection and is recommended to prevent HSV infections.[160] Nonoxynol-9, a spermicide that has in vitro anti-HSV activity, is ineffective in the prevention of established genital HSV infection and may actually increase the risk of transmission of HSV by causing genital ulceration.[190]

Complications

CASE 72-15

QUESTION 1: M.F. is a 23-year-old, sexually active female student with a history of frequent and severe recurrences of genital herpes since her initial infection 3 years ago. M.F. has tried numerous therapies, including suppressive and episodic antivirals. None of these therapies has provided M.F. with any relief of her symptoms, nor have they decreased the frequency of her recurrences. M.F. has read much in the lay press about herpes and is concerned about the possible complications of the disease, especially cervical cancer. What are the potential complications of herpes genitalis?

Previous research suggested that HSV-2 might be an oncogenic agent responsible for carcinoma of the cervix. However, a large longitudinal nested case-control study using nearly 20 years of seroepidemiologic and epidemiologic data combined with a meta-analysis concluded that it is very unlikely that HSV-2 is associated with the development of invasive cervical carcinoma.[191] Severe complications of herpes genitalis include central nervous system disease, such as meningitis and encephalitis, and disseminated disease.[142]

PREGNANCY

CASE 72-16

QUESTION 1: A.P., a 26-year-old woman in her 32nd week of gestation, was hospitalized with complaints of painful genital lesions, headache, fever, increased vaginal discharge, and dysuria of 1 week's duration. Multiple ulcerative lesions consistent with genital herpes were present on the cervix, vulva, labia minora, and thighs. How should A.P. be treated?

Herpes genitalis seropositivity in pregnant women occurs more frequently than in nonpregnant women, with 20% to 30% of all pregnant women having serologic evidence of HSV-2 infection.[192] When HSV is acquired by the mother near the time of delivery, transmission to the neonate can be 30% to 50% but less than 1% in those who acquired it early in pregnancy or had recurrent infection.[2] Unfortunately, a large proportion of those infections occurring during pregnancy are limited to the cervix and are totally asymptomatic, often eluding diagnosis.

Pregnant patients with a history of recurrent genital herpes should be examined carefully when they present in labor for evidence of active disease. The safety of systemic ACV and VCV in pregnant women has not been established in controlled trials, but the CDC cites the lack of documented fetal harm to assert that ACV can be used safely in all stages of pregnancy.[2] Thus, it is reasonable to recommend ACV to treat HSV in this patient. Some small studies suggest ACV administered for several weeks before delivery may decrease recurrent outbreaks and lessen the need for herpes-related cesarean section,[193] whereas a larger randomized clinical trial did not show a benefit in reducing the

---

need for a cesarean delivery with primary infection.[194] In general, it does seem that patients with symptomatic genital herpes benefit from cesarean section.[195] The manufacturer of Zovirax (ACV) maintains an extensive database of fetal complications related to ACV use. To date, no link between ACV and birth defects has been established.[196] The decision to treat HSV with ACV during pregnancy should depend on the clinical severity of infection. Fetal exposure data to FCV or VCV are limited. If the mother has an active herpes genitalis infection at the time of delivery (either active genital lesions or HSV-2 cervicitis), the baby should be delivered by cesarean section within 4 hours after the membranes have ruptured to prevent exposure of the neonate to the virus.[142] However, if no genital lesions are present at the time of labor, vaginal delivery may be recommended.[12] There is evidence that up to 70% of neonatal herpes cases occur in asymptomatic women, and the use of ACV or VCV after 36 weeks gestation may decrease clinical disease and viral shedding to the fetus.[197]

Neonatal herpes is a devastating systemic infection of the newborn, associated with high morbidity and mortality, especially when infected with HSV-2 versus

HSV-1.[198] HSV is usually transmitted to the newborn during passage through an infected birth canal, approximately 300 times greater than when HSV is not present.[195] The risk of transmission to the newborn is greatest in mothers who acquire an initial infection late in the third trimester and lower in mothers with recurrent infection or those who acquire herpes in the first trimester (25%–50% vs. <1% for preexisting infection).[198]

GENITAL WARTS

CASE 72-17

QUESTION 1: S.L., a 19-year-old woman, presents to the women's health clinic for her annual pelvic examination. One week later, her Pap smear is read as showing koilocytosis. A colposcopy is subsequently performed, revealing changes consistent with cervical flat warts. What is the cause of S.L.'s infection? How should she be managed?

Human papiloma virus (HPV) is the cause of genital warts, or condylomata acuminata. Types 6 and 11 account for more than 90% of genital warts.[199] Other types of HPV, including 16 and 18, account for as much as 70% of cervical cancer worldwide.[200],[201] They are associated with Pap smear changes, including koilocytosis and cervical dysplasia. In the United States, the seroprevalence of HPV 6, 11, 16, and 18 is 32.5% for women and 12.2% among men aged 14 to 59 years.[202]

Cervical intraepithelial neoplasia (CIN) is a common cervical cancer grading system using histologic changes to classify specimens in three categories: CIN-1, -2, and -3. The higher the number, the greater the chance of progressing to invasive cervical cancer. Most new cases of HPV infection spontaneously regress but with progressive histologic changes, the chance of spontaneously regressing diminishes (CIN1, 60%; CIN2, 30%; CIN3, 10%).[203] Types of HPV are also classified as high risk, or those likely to cause cancer, and low risk, those less likely to cause cancer. HPV types 16, 18, 31, 33, 45, 52, and 58 are considered high risk and types 6 and 11 are low risk, the latter mostly resulting in genital warts. In women, visible warts occur on the labia, introitus, and vagina. Subclinical lesions also commonly occur on these sites and on the cervix, as in S.L.'s case. They are visible only by colposcopy after applying acetic acid. Men can sexually transmit HPV infections to women as well as exhibit genital warts, and anal and penile cancer associated with oncogenic HPV types, especially type 16.[204] The goal of HPV therapy is the removal of symptomatic warts. Several therapeutic options are available and include patient-administered treatments to visible warts, such as podofilox 0.5% solution or gel, imiquimod 3.75% and 5% cream and sinecatechins 15% ointment; provider-administered products include topical treatments (podophyllin 10%–25%, trichloroacetic acid 80%–90%, and cryotherapy), surgery (laser or scalpel), and intralesional interferon.[12] In a recent meta-analysis, locally applied interferon showed a 44% lesion clearance compared with 27.4% for systemic interferon.[205] None of these treatments can eradicate HPV infection or alter the natural history of HPV. It is important to individualize therapy, considering location and number of warts, patient preference, cost, and convenience.

Podophyllin, compounded as a 10% to 25% solution in tincture of benzoin, is applied by the health care provider to visible warts. After application, it is washed off 3 to 4 hours later and then reapplied once or twice a week until the warts have disappeared. Podofilox 0.5% solution or gel, the active component of podophyllin resin, may be applied by the patient with a cotton swab, or podofilox gel with a finger, to visible genital warts twice a day for 3 days, followed by 4 days of no therapy. A total of four cycles, 0.5 mL/day, or application of an area larger than 10 cm^2 should not be exceeded. Podofilox solution is not suitable for use with perianal warts; the gel is more practical for this region. Podophyllin is potentially neurotoxic if absorbed in large amounts. Podofilox has the advantage over podophyllin resin in that it has a longer shelf life, does not need to be washed off, and has less systemic toxicity.[206] Therefore, it should be applied in limited doses and should also be avoided in pregnancy. The rate of wart recurrence after podophyllin therapy is extremely high, probably 50%. With the high cost of clinic care and the high recurrence rate, home treatment of HPV with podofilox solution may be more cost effective and equally efficacious.[207]

Imiquimod induces cytokines and activates the cell-mediated immune system. In initial trials, complete clearance of warts took place in 37% to 50% of immunocompetent patients, but up to 20% experienced recurrence.[208] The 5% cream is optimally applied by finger at bedtime 3 times per week and the 3.5% cream once daily for up to 16 weeks.[209],[210] It is usually left on for 6 to 10 hours before it is washed off with soap and water. Imiquimod may take as long as 8 weeks before warts are cleared. Mild-to-moderate local irritation occurs in more than half of the patients who use it, especially when used daily instead of 3 times weekly as directed. The cream may weaken condoms and diaphragms.

Sinecatechins are green-tea extracts that contain active catechins with purported immunostimulatory, antiprofliferative, and antitumor properties. In the United States, a 15% topical ointment is available. There are limited data on this product, but literature suggests it may be more effective than imiquimod or podofilox by clearing up to 55% of external genital warts.[211] It is applied by finger directly to the wart 3 times a day up to 16 weeks with the most common side effects being local erythema, pruritus, burning, and pain.[12]

Cryotherapy by application of liquid nitrogen can be more effective than podophyllin, but it requires special equipment and highly trained personnel. Pain and skin blistering after treatment is common. Cryotherapy is associated with minimal systemic toxicity and is useful against oral, anal, urethral, and vaginal warts.

Trichloroacetic acid (80%–90%) is used topically in the treatment of some genital warts, but its efficacy is uncertain. To date interferons are not recommended because of expense and toxicity. Cases refractory to topical drug therapy should be considered for surgical treatment.

Prevention

In 2006, the first vaccine to prevent HPV types 6, 11, 16, and 18 was approved in the United States. This quadrivalent vaccine was tested in women from 15 to 26 years of age and demonstrated 98% to 100% protection against HPV types contained in the vaccine.[212,213] In males, the quadrivalent vaccine efficacy was 62.1% to 89.4% against genital warts, depending upon previous HPV exposure, leading to its approval for men and boys 9 to 26 years old.[214] Using bridging data, it is estimated that 99% to 100% of 9- to 15-year olds will seroconvert. In 2014, a 9-valent HPV vaccine was approved to replace the quadrivalent vaccine. The extra 5 types (31, 33, 45, 52, and 58) add 15% more cervical cancer coverage protection to the 66% covered by types 16 and 18 in the quadrivalent.[215] This three-dose series can be given as early as 9 years of age, but it is CDC recommended at 11 to 12 years as part of a routine adolescent health care visit and ideally before commencement of sexual activity. Because there are more than 30 types of HPV associated with anogenital disease, a previous HPV infection is not a contraindication to vaccination. It is also important to note that receipt of the HPV vaccine does not change the recommendation for Pap smears. Lastly, it should not be considered a therapeutic vaccine as it has no impact on active HPV infection.

VACCINES

Prevention and control of STDs have largely revolved around education and antimicrobials. Immunization, however, holds the promise of protecting large numbers of people before they are at risk for STDs as well as targeting those who already have the infection. Hepatitis B is an example of an STD with a highly effective vaccine that is now mandatory for school-aged children. The nine-valent HPV vaccine is gaining momentum and a bivalent (HPV 16 and 18) is also approved by the FDA, but the latter is not indicated for prevention of genital warts. Herpes simplex vaccines have been extensively studied, but no candidate vaccine has been submitted for approval.

Osteomyelitis and Septic Arthritis

Jacqueline L. Olin, Linda M. Spooner, and Karyn M. Sullivan

CORE PRINCIPLES

OSTEOMYELITIS

	CORE PRINCIPLES	CHAPTER CASES
1	Acute hematogenous osteomyelitis is characterized by the abrupt onset of localized pain and tenderness at a single site, fever, and increased inflammatory markers (erythrocyte sedimentation rate, C-reactive protein). Imaging techniques and blood and bone cultures (if done) may reveal findings consistent with bone changes in osteomyelitis and the responsible pathogen.	**Case 73-1 (Questions 1, 2), Table 73-1**
2	Initial empiric antibiotic therapy for acute hematogenous osteomyelitis should be directed at gram-positive cocci, including methicillin-resistant Staphylococcus aureus (MRSA). Protein binding and bone concentrations of antibiotics are not critical factors in predicting successful treatment, as long as the responsible pathogen is susceptible to the chosen therapy, and treatment is given in high doses for long duration.	**Case 73-1 (Question 3), Table 73-2**
3	If blood or bone cultures grow the likely pathogen, then therapy should be de-escalated when possible based on organism susceptibilities. Assuming no allergies, methicillin-sensitive Staphylococcus aureus (MSSA) should be treated with oxacillin or nafcillin. The overall duration of therapy (by intravenous [IV] route and possibly orally) should be at least 4 weeks.	**Case 73-1 (Questions 4–6), Tables 73-2, 73-3**
4	Osteomyelitis secondary to a contiguous focus of infection typically occurs after trauma and the consequent orthopedic corrective surgery. Common symptoms are pain, tenderness, erythema, and drainage at the site of injury or infection. Imaging studies usually show bone changes consistent with infection.	**Case 73-2 (Questions 1, 2), Table 73-1**
5	Secondary osteomyelitis is often polymicrobial. Surgical efforts should be instituted to reassess the site of bone injury and infection, with deep tissue or bone samples obtained for culture. Treatment is IV therapy for at least 4 weeks, and the antibiotics chosen should depend on the cultured organisms and their antibiotic susceptibilities.	**Case 73-2 (Questions 3, 4)**
6	Osteomyelitis associated with vascular insufficiency most often occurs in patients with diabetes mellitus. Neuropathy and impaired blood flow lead to the development of chronic lower extremity cellulitis and underlying	**Case 73-3 (Questions 1, 2)**

	osteomyelitis. Multiple gram-positive and gram-negative aerobic and anaerobic bacteria may be involved; thus, initial empiric treatment typically includes vancomycin and an antipseudomonal beta-lactam. Definitive therapy should be based on the results of deep surgical cultures. Duration of treatment should be 6 or more weeks, with chronic suppressive therapy considered thereafter.	
⑦	Chronic osteomyelitis can present years later at a site of previous bone infection and is usually characterized by a draining sinus tract from bone to skin. Chronically infected dead bone is involved, and surgery is important in removing necrotic bone when possible. Chronic osteomyelitis is often polymicrobial, and the same organism (especially S. aureus) that was causative of a previous bone infection could still be involved in chronic infection. High-dose IV therapy directed at the results of bone cultures for at least 6 weeks is recommended to offer the best chances of preventing the extension of infection to adjacent uninfected bone.	**Case 73-4 (Questions 1–4)**

⑧	Prosthetic joint infection with adjacent bone osteomyelitis usually requires surgical removal of the infected prosthesis for cure. Antibiotics should be directed at the cultured bacteria from a joint aspirate or from deep surgical specimens. The most common pathogens are S. aureus and coagulase-negative staphylococci. In a situation in which the prosthesis cannot be totally removed, lifelong, chronic suppressive oral therapy should be considered.	**Case 73-5 (Questions 1–3)**

SEPTIC ARTHRITIS

①	Nongonococcal septic arthritis is characterized by fever, and the acute onset of joint pain and effusion in a single joint. Infection is typically acquired hematogenously from an originating site that may not always be easily identified. S. aureus is the most common pathogen. Duration of treatment should be 6 weeks, with oral therapy for the final 2 weeks.	**Case 73-6 (Questions 1, 2)**
②	Neisseria gonorrhoeae is the most common cause of polyarticular arthritis in a young, sexually active adult. Skin lesions may also be present in disseminated gonococcal infection (DGI). The diagnosis is frequently based on the clinical syndrome and sexual history, because joint fluid aspirate and blood cultures are frequently negative. Intravenous ceftriaxone is the treatment of choice and should be continued for 1 to 2 days after improvement begins. Treatment duration is 7–14 days.	**Case 73-7 (Questions 1–3)**

OSTEOMYELITIS

Osteomyelitis is an inflammation of the bone marrow and surrounding bone associated with infection. Any bone can be involved, and substantial morbidity is possible even with early diagnosis and treatment. Despite the continued refinement of diagnostic procedures (e.g., radionuclide imaging, computed tomography, magnetic resonance imaging), advances in antimicrobial therapy, and the use of prophylactic antibiotics before orthopedic procedures, osteomyelitis continues to be difficult to cure.

Osteomyelitis can affect all age groups. The most common causative microorganisms of acute osteomyelitis have historically been streptococci and staphylococci. Staphylococcus aureus remains the most causative organism, accounting for more than 50% of all cases, although the prevalence of infection caused by methicillin-resistant S. aureus (MRSA) is increasing across all age-groups. Additionally, osteomyelitis caused by gram-negative and anaerobic bacilli is becoming more common.[1]

Bone may be infected by three routes: hematogenous spread of bacteria from a distant infection site, direct infection of bone from an adjacent or contiguous source of infection, and infection of bone secondary to vascular insufficiency. Table 73-1 summarizes characteristics associated with osteomyelitis.[1–3] Patients with recurrent osteomyelitis are considered to have chronic osteomyelitis.

Bone Anatomy and Physiology

The bone is divided into three sections: the epiphysis, located at the end of the bone; the metaphysis (adjacent to the epiphysis and part of the epiphyseal growth plate); and the diaphysis (midsection of the bone). The rapidly growing area of the bone is supported by many blood vessels. Surrounding most of the bone is a fibrous, cellular envelope. The external portion of this envelope is the periosteum, and the internal portion is the endosteum.

Blood vessels that supply bone tissue are located predominantly in the epiphysis and metaphysis of the bone. Nutrient arteries enter the bone at the metaphyseal side of the epiphyseal growth plate and lead to capillaries that form sharp loops within the growth plate. These capillaries lead to large sinusoidal veins that eventually exit the metaphysis through a nutrient vein. Within the sinusoidal veins, blood flow is slowed considerably, and infection is possible with bacterial colonization.[4]

Differences in the vasculature of bone in different age groups lead to different forms of osteomyelitis. In neonates and adults, vascular communications are present between the metaphysis and epiphysis, which can allow infection to spread from bone to the adjacent joint. During childhood, however, this area often is protected from infection because the epiphyseal plate separates the vascular supply for these two regions.[4]

Hematogenous Osteomyelitis

Hematogenous osteomyelitis predominantly occurs in prepubertal children but may be seen in older adults, patients with indwelling central catheters, and intravenous drug users.[1] Osteomyelitis in children tends to be acute, hematogenous, and is often responsive to antibiotic therapy alone. In comparison, osteomyelitis in adults tends to be subacute or chronic, commonly results from trauma, infection of prosthetic devices, or other insult, and often requires surgical debridement in addition to antimicrobial therapy.[1–3]

Infection in children develops primarily in the metaphysis of the rapidly growing long bones of the body where the slowed blood flow allows bacteria to colonize and multiply. The acute infectious process (e.g., edema, inflammation, small vessel thrombosis) increases bone pressure, which compromises blood flow and eventually leads to necrosis. Released cytokines alter bone integrity by promoting osteoclast activity. Eventually, the elevated pressure and necrosis cause devitalized bone to fragment from healthy bone (sequestra). With continued spread of the infection into the outer layers of the bone and soft tissue, abscess and draining sinus tracts form.[1,3]

Hematogenous infection in children most commonly occurs in the long bones with a single focus in the femur and tibia.[1] Hematogenous osteomyelitis in neonates is an especially serious disease that often involves multiple bones, especially the long bones. Rapid infection spreading across the epiphyseal plate to the adjacent joint can lead to septic arthritis, necessitating immediate and aggressive treatment. Vertebrae involvement is seen more frequently in adults.[1–3]

The most common organism causing hematogenous osteomyelitis is S. aureus, responsible for up to 85% of pediatric cases.[4] The emergence of both hospital- and community-associated strains of MRSA has challenged the management of osteomyelitis. MRSA infections are associated with an increased risk of antibiotic treatment failures and complications, including abscess formation, deep vein thrombosis, and septic emboli.[5] Gram-negative bacilli (Escherichia coli, Klebsiella, Proteus, Salmonella, and Pseudomonas) are responsible for an increasing number of cases of osteomyelitis as well. Pseudomonas aeruginosa is more commonly seen in patients with indwelling central catheters and in intravenous (IV) drug users, whereas S. aureus and Salmonella species are common causes in patients with sickle cell anemia.[1]

Table 73-1

Features of Osteomyelitis

Feature	Hematogenous	Adjacent/Contiguous Site of Infection	Vascular Insufficiency
Usual onset: pediatric or	Predominantly pediatric	Adult	Adult

adult			
Sites of infection	Tibia, femur (children); vertebrae (adults)	Femur, fibula, tibia, skull, mandible	Foot
Risk factors	Bacteremia	Surgery, trauma, cellulitis, joint prosthesis	Diabetes, peripheral vascular disease
Common bacteria	S. aureus, gram-negative bacilli; usually one organism	S. aureus, streptococci, gram-negative bacilli, anaerobic organisms; often polymicrobial	S. aureus, coagulase-negative staphylococci, streptococci, gram-negative bacilli, anaerobic organisms; often polymicrobial
Clinical findings	Fever, chills, local tenderness, swelling; limitation of motion	Fever, warmth, swelling; unstable joint	Pain, swelling, drainage, ulcer formation

Clinical features of hematogenous osteomyelitis vary, depending on the patient's age and the infection site. In children, infection usually is characterized by an abrupt onset of high fever and chills, localized pain, tenderness, and swelling. Systemic symptoms often are absent in neonates, potentially delaying the diagnosis. A diagnosis, therefore, must be made on the basis of localized symptoms such as edema and restricted limb movement. Systemic symptoms are also less common in adults, although patients with vertebral osteomyelitis can present with the insidious onset of localized back pain and tenderness.[1],[3]

Acute Osteomyelitis

USUAL CLINICAL PRESENTATION

CASE 73-1

QUESTION 1: L.D., a 7-year-old girl, is unable to go to school today because of fever and worsening leg pain. Her upper left leg started to hurt 3 to 4 days ago, and last night she began limping. Her parents report no history of trauma to the area. Her past medical history is significant only for two episodes of otitis media at ages 2 and 5. In the pediatrician's office, maximal tenderness is localized over the left distal femur without knee joint effusion. No signs of swelling, warmth, or trauma are seen. Her white blood cell (WBC) count is 8,000/μL with a normal WBC differential. Plain radiographic studies of the left leg are normal, but the erythrocyte sedimentation rate (ESR) is 58 mm/hour (normal ≤30 mm/hour). Two blood samples are obtained for culture, and L.D. is sent home with directions for bed rest and use of acetaminophen as needed for fever. Two days later, she is admitted to the hospital with severe pain and tenderness in her left leg and a fever of 38.8°C. The blood cultures obtained 2 days ago are positive for S. aureus with susceptibilities still pending. C-reactive protein (CRP) is 14 mg/dL (normal, <2 mg/dL). Another plain radiographic study is normal, but a magnetic resonance imaging (MRI) scan reveals inflammation in her left distal femur. What findings in L.D. are consistent with hematogenous osteomyelitis?

L.D. displays the usual signs and symptoms of acute hematogenous osteomyelitis in children. She is a previously healthy child who experienced acute localized pain and tenderness of the left distal femur, abrupt onset of high fever, and an elevated ESR and CRP. Her plain radiographic studies were normal on two occasions; however, destructive changes to bone often do not appear on plain radiographs for at least 10 to 14 days after onset of infection.[1] Hence, a normal plain film does not rule out acute osteomyelitis if obtained within the first 2 weeks of infection. Diagnosis includes radionuclide imaging (bone scans), computed tomography (CT), or MRI.[1,4] MRI is more sensitive than CT for the assessment of soft tissue and detecting early bone marrow edema; however, it often requires sedation for children.[4] The sensitivity of bone scan detection of osteomyelitis has been lowest when the infection was caused by community-associated MRSA (CA-MRSA).[4] L.D.'s MRI scan on hospitalization detected inflammation in the left distal femur. Although L.D. did not have a bone biopsy sent for culture, her clinical picture, a positive MRI scan, and blood cultures positive for S. aureus establish the diagnosis of osteomyelitis. The specific event that caused bacteremia with dissemination to bone is unknown, as is often the case in children.[4]

Laboratory tests that should be routinely obtained in every child suspected of having osteomyelitis include a complete blood count (CBC), ESR, and serum CRP. Although these tests are not specific for the diagnosis of osteomyelitis, they help confirm the clinical diagnosis. An increased WBC count is consistent with osteomyelitis, but leukocytosis is absent in many children with osteomyelitis at the initial examination. Thus, L.D.'s WBC count of 8,000/μL is not unusual. In adults, leukocytosis is more common in an acute infection rather than with recurrent or chronic disease. Both ESR and CRP are nonspecific markers of systemic inflammation when elevated.

Predisposing factors for hematogenous osteomyelitis include any risk factors for bacteremia (e.g., indwelling catheters such as hemodialysis shunts and chronic central venous catheters). Other risk factors that can potentially lead to bacteremia and subsequently hematogenous osteomyelitis include IV drug use and a distant focus of infection in the gastrointestinal or urinary tract. None of these factors exist in L.D. In children such as L.D. who have no history of trauma, fractures, or penetrating injury, the most common cause of acute hematogenous osteomyelitis is S. aureus and the possibility of CA-MRSA must be considered.[1,5,6]

PATIENT WORKUP

CASE 73-1, QUESTION 2: What additional patient and diagnostic information should be obtained before L.D. receives her first dose of antibiotics?

Before L.D. receives antibiotic therapy, she should be assessed for drug allergies, especially penicillin allergy. Patient interviews, discussions with her parents, and a comprehensive review of her medical record are necessary, especially with a history of allergy. Details of an allergic reaction, including symptoms, onset of the reaction, probable causative agent, treatment, and exposure to related antimicrobials should be evaluated.

Cultures of blood and bone aspirate material optimally identify the pathogen and must be part of the initial workup prior to the start of antibiotics. Cultures taken after antibiotics have been initiated are often negative. Positive blood cultures are seen in 33%–50% of pediatric bone and joint infections.[6]

In L.D.'s case, the positive blood culture and MRI establish the diagnosis of osteomyelitis. If the blood cultures had been negative, however, a bone aspirate would be recommended to identify the pathogen.[1] Once material has been obtained for culture, empiric antibiotic therapy should start as soon as possible.

TREATMENT

Empiric Antibiotic Therapy

CASE 73-1, QUESTION 3: L.D. has no history of drug allergies. She took amoxicillin for the previous episodes of acute otitis media without incident. What empiric antibiotic(s) should be started? What is the relevance of bone concentrations or protein binding of antibiotics in the selection of therapy for osteomyelitis?

The chosen agent should be administered IV at high doses to optimize drug concentration in infected bone. Treatment should be initiated as soon as possible to improve the chances for complete eradication of infection and to avoid the need for surgery. Thus, empiric antibiotic therapy is often administered while bacterial cultures are pending or before antibiotic susceptibility results are known.

Although cultures are pending or with negative cultures, the age of the child can predict the likely pathogen and guide empiric antibiotic selection. For example, S. aureus and Streptococcus species are commonly responsible for osteomyelitis in the neonate.[1] Kingella kingae, a facultatively anaerobic, gram-negative hemolytic bacillus, is being detected with increasing frequency in children under 3 years of age, especially in the day care setting.[7],[8] Table 73-2 summarizes the common causative organisms of acute hematogenous osteomyelitis in children and recommended drugs and doses for treatment.[2],[4,9,10]

Considering the epidemiology of L.D.'s infection and the blood cultures, she should be treated for S. aureus osteomyelitis. In both children and adults, the number of acute osteomyelitis cases caused by MRSA continues to increase.[4],[6] Empiric IV vancomycin should be administered pending susceptibility results. Alternative empiric therapy for L.D. with MRSA coverage includes daptomycin or linezolid.[9] Due to limited clinical experience, these two agents should be reserved for vancomycin-intolerant cases. Clindamycin is not an option for L.D., but may be used empirically for stable patients without bacteremia or intravascular infection.[9]

The importance of antibiotic bone concentration when treating osteomyelitis is unclear, and bone concentrations do not always predict outcome of therapy.[2],[11] Theoretically, protein binding could influence clinical efficacy because free drug is thought to diffuse from plasma into bone tissue and protein-bound drug does not.

However, cefazolin (for sensitive gram-positive cocci) and ceftriaxone (for sensitive gram-negative rods and streptococci), both highly protein-bound drugs, are well-established treatments for osteomyelitis when appropriate doses and duration are used. Therefore, antibiotic bone concentrations and protein binding of antibiotics (in appropriate doses) are not significant factors in the selection of appropriate therapy for osteomyelitis.[2],[11]

Directed Antibiotic Therapy

CASE 73-1, QUESTION 4: The S. aureus grown from L.D.'s blood culture is methicillin sensitive. Considering these results, what is the optimal antibiotic regimen? Would other antibiotics given less frequently also be adequate?

L.D. is not allergic to penicillin. Although vancomycin is active against MSSA, it is inferior to β-lactams; thus, β-lactam-based therapy should be used for susceptible organisms.[1],[6] De-escalating from vancomycin to oxacillin (or nafcillin) at 150 mg/kg/day every 6 hours is appropriate.[2] Nafcillin and oxacillin are therapeutically equivalent and are given in similar doses; therefore, selection typically depends on hospital formulary considerations. Her prior exposure to amoxicillin is irrelevant except to establish the absence of a penicillin allergy.

Continuing to treat L.D. with IV oxacillin (or nafcillin) every 6 hours follows treatment recommendations for MSSA osteomyelitis. Antistaphylococcal penicillins are effective therapy with appropriate doses and duration. Changing L.D. to cefazolin would allow slightly less frequent dosing (every 8 hours), a potential advantage for home treatment. Vancomycin use should be discouraged in L.D.'s case because cultures revealed a methicillin-sensitive organism, and vancomycin is more likely to be associated with treatment failure.[1],[6] In the absence of susceptibility results or of methicillin resistance, IV vancomycin would be required for the duration of therapy. Although the logistics of outpatient therapy in L.D. are being investigated, she should remain on oxacillin while in the hospital.

Duration of Therapy

CASE 73-1, QUESTION 5: Both of L.D.'s parents are employed, and their work schedules prevent them from leaving their jobs to transport her to an outpatient antibiotic treatment center. Is L.D. a candidate for outpatient IV antibiotic therapy at home, or is oral antibiotic treatment an option? Must L.D. remain in the hospital to receive her oxacillin?

Initially, all patients should receive IV antibiotics because early, aggressive therapy offers the best chance to cure the infection. L.D., however, does not necessarily need to stay in the hospital for the duration of therapy. A peripherally inserted central catheter (PICC) can be placed, and antibiotics can be administered. The decision to use home IV antibiotic administration must be decided in concert with L.D.'s parents. If L.D.'s parents do not have the resources or are unwilling to oversee IV treatment at home, L.D. should remain hospitalized for a minimum of 1 week to assess the efficacy of IV treatment. Transition to oral therapy should be considered at discharge due to the frequency of PICC line complications and the cost and inconvenience of several weeks of IV therapy at home.[7],[12]

As discussed below in Question 6, L.D. can complete most of her treatment with oral antibiotics, but oral therapy should not be given until the effectiveness of IV therapy can be assessed. Children with uncomplicated acute osteomyelitis are candidates for oral therapy when clinically improved, and the CRP has normalized, typically between 3 and 7 days.[13],[14] Total duration of antibiotic therapy should be 3–4 weeks; however, current IDSA guidelines recommend 4 to 6 weeks of therapy for children with MRSA osteomyelitis.[9],[13,14] Neonatal cases warrant 4 weeks of IV antibiotics.[14]

Table 73-2

Empiric Intravenous Antibiotics for Acute Osteomyelitis in Children

			Dose	
Host	**Likely Organisms**	**Antibiotics**	**(mg/kg/day)**	**(doses/day)**
Neonate	Staphylococcus aureus Group B streptococci Gram-negative bacilli	Oxacillin (or nafcillin) with	25–50	2–4
		Cefotaxime	50	2–4
<3 years	S. aureus	Vancomycin or	40–60	4
		Linezolid or	30	3
		Daptomycin	6	1
	Haemophilus influenzae type b	Oxacillin (or nafcillin) with	150–200	4
		Cefotaxime	100–180	4–6
	Kingella kingae	Cefazolin or	50–100	3–4
		Cefuroxime	100–150	3–4
≥3 years	S. aureus	Vancomycin or	40–60	4
		Linezolid		
		≤12 years	30	3
		>12 years or	600 mg dose	2
		Daptomycin or	6	1
		Oxacillin (or nafcillin) or	150–200	4
		Cefazolin or	50–100	3–4
		Clindamycin	40	3–4
After puncture	P. aeruginosa	Ceftazidime	100–150	3

wound through shoe				
Child with sickle cell disease	Salmonella sp. S. aureus	Oxacillin (or nafcillin) with	150–200	4
		Cefotaxime or	100–180	4–6
		Vancomycin with	40–60	4
		Cefotaxime	100–180	4–6

Oral Antibiotics

CASE 73-1, QUESTION 6: After 1 week of IV nafcillin, L.D. is afebrile and reports that the pain and tenderness in her left leg are much improved. Her ESR is 40 mm/hour, and CRP is 6 mg/dL. The plan is to switch L.D. to oral antibiotics to complete a 4-week course of therapy at home. What would be an appropriate oral antibiotic regimen for L.D.? How often should she return to the clinic for evaluation?

Again, oral antibiotics are only appropriate if a clear clinical response has occurred within the first week of IV therapy, the patient's parents are aware of the vital importance of compliance, and the patient can swallow and tolerate oral therapy.

Assuming her parents agree to supervise treatment outside of the hospital, L.D. is a candidate for oral therapy. She has responded promptly to the IV therapy: her symptoms have improved, and the ESR and CRP are trending downward. Oral therapy will be effective only if L.D. consistently takes her medications; therefore, assurances must be in place to facilitate compliance. L.D.'s parents have made arrangements with her teacher to help her take her oral antibiotic during the day.

L.D. can complete her 4-week course of antibiotics with oral cephalexin capsules or suspension, which is more palatable (and is usually better tolerated) than dicloxacillin suspension. Cephalexin should begin at 37.5 mg/kg/dose every 6 hours. Weekly follow-up is necessary to monitor compliance and clinical response to therapy. Parenteral therapy should be reinitiated, and re-evaluation is warranted if L.D.'s compliance is not optimal, symptoms recur, or ESR or CRP increases.[4],[14] Oral antibiotic doses for children with osteomyelitis are summarized in Table 73-3.[4],[9]

Osteomyelitis Secondary to a Contiguous Source of Infection

CLINICAL PRESENTATION

CASE 73-2

QUESTION 1: M.K., a 30-year-old man, suffered an open left femur fracture 3 weeks ago in a motorcycle accident. His fracture was set by open reduction and internal fixation. M.K. had received prophylactic piperacillin/tazobactam for soft-tissue coverage of the open fracture for 72 hours after hospitalization. His postoperative course was unremarkable until yesterday when he experienced left leg pain and spontaneous drainage from the surgical wound. On presentation, his left thigh is tender, warm, swollen, and erythematous, but he is afebrile. Laboratory data, including WBC count, serum creatinine, and blood urea nitrogen (BUN), are normal, but the ESR is 38 mm/hour and CRP is 8 mg/dL. Plain bone films and bone MRI show inflammation and nonhealing of the femur fracture. What findings in M.K. are characteristic of secondary osteomyelitis?

Table 73-3

Oral Antibiotic Doses for the Treatment of Osteomyelitis in Children

Drug	Dose (mg/kg/day)	Doses/day
Penicillin V	125	6
Dicloxacillin	100	4
Amoxicillin	100	4
Cephalexin	150	4
Clindamycin	40	3
Linezolid		
≤12 years	30	3
>12 years	600 mg dose	2

Few of the systemic signs and symptoms usually associated with acute osteomyelitis are seen in secondary osteomyelitis. The most common subjective complaint in acute contiguous osteomyelitis is pain in the area of infection, localized tenderness, swelling, erythema, and drainage. Considering several weeks might pass before the patient becomes symptomatic, radiographic studies at the time of diagnosis might reveal abnormalities consistent with bone deterioration.[1]

M.K.'s case is consistent with osteomyelitis secondary to a contiguous focus of infection. Infection likely is at the site of surgical repair of the left femur fracture. M.K.'s localized symptoms, along with the absence of fever and leukocytosis, are characteristic of secondary osteomyelitis. In these cases, bone becomes infected from an exogenous source or through spread of an infection from adjacent tissue to bone. Infection can result from any trauma with or without subsequent orthopedic procedure to fix a bone fracture. The bones most commonly involved are the tibia, fibula, femur, and hip.[1]

Unlike hematogenous osteomyelitis, which occurs mostly in children, acute contiguous infection occurs more often in adults. This finding is explained by the higher incidence of precipitating factors within this age-group, such as hip fractures, orthopedic procedures, oral cancers, sternotomy incisions for cardiac surgery, craniotomies, and trauma.[1] Other conditions potentially associated with secondary osteomyelitis include gunshot wounds, punctures, or soft-tissue infections.

Common Pathogens

CASE 73-2, QUESTION 2: What organisms are most likely causing infection in M.K.?

Whereas hematogenous osteomyelitis usually involves a single pathogen, polymicrobial infection is common in contiguous-spread osteomyelitis. Although S. aureus is the most common pathogen, it is often part of a mixed infection. Other common pathogens include Pseudomonas, Proteus, Streptococcus, and Klebsiella species, E. coli, and S. epidermidis. Most cases of osteomyelitis involving the mandible, pelvis, and small bones (e.g., those of the hands and feet) are caused by gram-negative organisms. Pseudomonas often is isolated from infections after puncture wounds of the foot.[1] Anaerobes also are associated with contiguous-spread osteomyelitis, and most commonly isolated are Bacteroides species and anaerobic cocci. Possible predisposing factors include previous fractures or injuries resulting from human bites. Adjacent soft-tissue infections can also lead to anaerobic bone infections, as in the case of sacral osteomyelitis secondary to severe decubitus ulcers. To identify the true pathogen(s), M.K. should have surgical re-evaluation and a biopsy of involved bone at the probable site of infection.[1] Bone films and the MRI scan will help localize the possible infectious process to direct the surgical biopsy.

Initial Treatment

CASE 73-2, QUESTION 3: M.K. returns to the operating room for surgical exploration, and bone tissue is obtained for culture. He has no drug allergies and weighs 90 kg. The initial postoperative antibiotic order is for vancomycin, 1 g IV every 12 hours. Is this adequate antibiotic treatment for M.K.?

M.K. has had surgery to obtain bone material for culture because cultures of adjacent wound or sinus tract material are not always predictive of the bacteria actually infecting the bone.[1] Broad empiric antibiotic coverage is necessary because S. aureus and polymicrobial gram-negative aerobic bacilli most likely are causing this infection.[1]

M.K. has been started on vancomycin for possible MRSA infection while awaiting results of bone tissue cultures. Many clinicians target goal trough concentrations between 15 and 20 mcg/mL for osteomyelitis.[9] Given his normal renal function and weight, M.K. will likely require at least 1.5 g IV every 12 hours of vancomycin (15 mg/kg/dose).

To cover possible pathogenic gram-negative aerobic bacilli, a third- or fourth-generation cephalosporin (cefotaxime, ceftriaxone, ceftazidime, or cefepime) or a quinolone (ciprofloxacin, levofloxacin) could be added. The choice of agent should, in part, be based on local susceptibility patterns. In locations in which quinolone gram-negative resistance approaches 30%, these agents have limited utility.

Anaerobic coverage should be initiated if an anaerobe is cultured from bone or anaerobes are suspected. Vancomycin has activity against gram-positive anaerobes, but not against the gram-negative anaerobe, Bacteroides fragilis. If B. fragilis is cultured from bone, additional therapy with metronidazole is indicated. Alternatively, combined, broad-spectrum aerobic (including Pseudomonas) and anaerobic gram-negative coverage could be provided by a β-lactam/β-lactamase inhibitor combination therapy with piperacillin/tazobactam or a carbapenem.

Although cultures are pending, M.K.'s antibiotic regimen is changed to vancomycin 1.5 g IV every 12 hours and cefepime 2 g IV every 8 hours.

DIRECTED THERAPY

CASE 73-2, QUESTION 4: The bone biopsy from M.K. grows MRSA that is sensitive to vancomycin, linezolid, and trimethoprim/sulfamethoxazole. His leg pain is no worse than it was 2 days ago, and he remains afebrile. How should M.K. now be treated? Is he a candidate for oral therapy?

Because no gram-negative organisms grew on culture, cefepime may be discontinued. Therapy should be directed against the MRSA. Thus, it is justified to continue treating M.K. with vancomycin (1.5 g IV every 12 hours) as long as he is monitored closely, following his symptoms, a vancomycin trough level between

---

15 and 20 mg/L, weekly ESR or CRP concentrations, complete blood count, and metabolic panel. Vancomycin can be administered at home with the appropriate home health care. Studies have shown that oral antibiotics can achieve adequate concentrations in bone. Based on clinical improvement and provider preference, M.K. can be transitioned to oral linezolid (600 mg twice daily) or trimethoprim-sulfamethoxazole TMP-SMX (4 mg/kg/dose [TMP component] twice daily) in combination with rifampin (600 mg once daily) for a minimum of 8 total weeks of therapy.[9] He should be followed closely for at least 2 years to detect recurrent infection.

Osteomyelitis Associated with Vascular Insufficiency

CLINICAL PRESENTATION

CASE 73-3

QUESTION 1: M.S., a 55-year-old woman, presents to the diabetes clinic with an ulcer 2 cm wide × 1 cm deep on the left lateral aspect of her foot that she first noted a month ago. Her primary care physician had prescribed a 2-week course of ciprofloxacin and gave her instructions for regular wound care. A few days before her clinic visit, the callus surrounding the ulcer cracked open and a small piece of bone protruded from the wound. She reports mild swelling and redness but denies any pain, fever, or chills. Her past medical history includes type 2 diabetes mellitus, hypertension, peripheral neuropathy, and chronic kidney disease requiring hemodialysis 3 times a week. Laboratory findings include WBC 5,200/μL with normal differential, BUN 56 mg/dL, serum creatinine 5.6 mg/dL, fasting blood glucose 240 mg/dL, hemoglobin A_{1c} (Hb A_{1c}) 12.4%, and ESR 45 mm/hour. What findings in M.S. are consistent with osteomyelitis secondary to vascular insufficiency?

M.S. has chronic lower extremity vascular insufficiency as a result of type 2 diabetes. Patients with impaired blood flow may develop osteomyelitis in the toes or small bones of the feet. Infection often first presents as cellulitis, as in M.S.'s case, progressing to deep ulcers and finally to the underlying bone.

Similar to contiguous-spread osteomyelitis, systemic signs of infection (e.g., fever and leukocytosis) are often absent in patients who experience bone infection secondary to vascular insufficiency. Local symptoms such as pain, swelling, and erythema usually predominate, but there are no specific clinical findings.[15]

M.S. may have a bone infection under the chronic, cutaneous ulcer on the bottom of her left great toe. Because of peripheral neuropathy, the skin lesion may not be painful, and poor blood supply to the site likely contributed to the development of a chronic infection and possibly secondary osteomyelitis. The true depth of an ulcer is not always clinically apparent so careful physical examination and evaluation of patient risk factors are essential for diagnosis.[15] Infection is suggested by her elevated ESR, fasting glucose (consistent with infection), and Hb A_{1c} (indicating uncontrolled diabetes). In addition, diabetic foot ulcers with an area larger than 2 cm^2 or that penetrate to bone are often predictive for underlying osteomyelitis.[15]

ANTIBIOTIC SELECTION

CASE 73-3, QUESTION 2: M.S. is admitted into the hospital for diagnostic workup, wound care, and antibiotics. Plain films show destruction of the distal left fifth metatarsal with bony changes consistent with osteomyelitis. Her wound is debrided, and material obtained from a bone biopsy is sent to the microbiology laboratory for cultures. She has no drug allergies and is started on vancomycin (1 g IV every 12 hours) and oral ciprofloxacin (750 mg every 12 hours). Is this appropriate initial, empiric therapy?

In many cases of osteomyelitis associated with vascular insufficiency, multiple pathogens can be cultured from surgical specimens or the wound. The most commonly isolated pathogen is S. aureus; however, gram-negative and anaerobic bacteria are also often recovered. The bacteria isolated from a wound or soft-tissue culture may not correlate with bacteria found in a concomitant bone biopsy.[15],[16] Therefore, empiric antibiotic therapy for osteomyelitis associated with vascular insufficiency should be active against both gram-positive and gram-negative aerobic bacteria and possibly anaerobes. No specific regimens have demonstrated superiority, so a broad-spectrum empiric regimen can be chosen based on local sensitivity patterns.[1] An antipseudomonal β-lactam (ceftazidime, cefepime) or quinolone (ciprofloxacin, levofloxacin) for gram-negative coverage is frequently used as an empiric regimen. If anaerobic bacteria are believed to be clinically involved (e.g., foul-smelling wound), metronidazole should be added to the regimen; alternatively an antipseudomonal β-lactam/β-lactamase inhibitor combination, such as piperacillin-tazobactam, can be used.

M.S. has risk factors for MRSA and resistant gram-negative bacilli because of her diabetes, hemodialysis, and recent course of antibiotics. The initial regimen of vancomycin and ciprofloxacin for M.S. is not optimal for several reasons. Because of her recent, prolonged ciprofloxacin exposure, a quinolone-resistant organism may be responsible for infection and a β-lactam-based antibiotic regimen would be more appropriate. Secondly, IV antibiotics should be used during initial treatment. Lastly, M.S. is dialysis-dependent, and the antibiotic regimen selected should be dose-adjusted according to her renal function. A more appropriate empiric regimen for M.S. would be vancomycin intermittently dosed based on serum drug concentrations and her dialysis regimen, and cefepime 1 g IV every 24 hours with the dose administered after dialysis on dialysis days.

Further antibiotic refinement should occur after the results of the deep wound swab culture are available. The optimal duration of IV therapy for diabetic foot osteomyelitis is patient-dependent, and some patients may require longer-term, oral suppressive therapy. The overall duration of antibiotic treatment can range from 6 weeks to many months depending on the degree of surgical debridement and the healing rate of the ulcer.[15] Oral linezolid (600 mg every 12 hours) has been used to treat MRSA osteomyelitis in diabetic patients, although long-term therapy can be associated with hematologic and neuropathic adverse effects.[17]

M.S. should be made aware that osteomyelitis associated with diabetic foot ulcers is difficult to treat. Despite adequate surgical debridement of the infection followed by appropriate treatment with long-term IV and oral antibiotic therapy, cure rates are low. Even minor amputations (one or two toes) are unsuccessful in eradicating infection. Radical surgical approaches, such as transmetatarsal, below-the-knee, or above-the-knee amputations, often are necessary to cure these infections.[1]

Chronic Osteomyelitis

CLINICAL PRESENTATION

CASE 73-4

QUESTION 1: J.F., a 52-year-old man, sustained a fracture of the right humerus in a farming accident 6 years ago. That fracture clinically healed without any immediate consequences; however, 1 year ago, a draining sinus tract developed at the site of the previous fracture without any antecedent events. He has taken various oral antibiotics during this last year, including amoxicillin and levofloxacin, which he stopped taking 2 months ago. Two weeks ago he noted increased sinus drainage, pain, swelling, and

---

erythema of his left upper arm, and levofloxacin was restarted. A swab culture of the sinus drainage grew S. epidermidis, E. coli, Peptostreptococcus micros, and Bacteroides species. Surgical debridement of bone and tissue was performed because of increased drainage and poor appearance of the wound. Gentamicin-impregnated polymethylmethacrylate (PMMA) beads were placed in the tissue adjacent to the debrided bone during surgery. Bone cultures grew Proteus mirabilis and B. fragilis. The Proteus was resistant to ampicillin, cefazolin, levofloxacin, and tigecycline, but sensitive to cefotaxime, ceftriaxone, imipenem, gentamicin, and trimethoprim-sulfamethoxazole. Antibiotic susceptibilities for the Bacteroides were not tested. What aspects of J.F.'s case are characteristic of chronic osteomyelitis?

Inadequate treatment of an acute episode of osteomyelitis can lead to formation of necrotic, infected bone and recurrent symptoms consistent with chronic disease. Despite appropriate initial therapy, osteomyelitis can reactivate, even with organisms different from the initial episode. Some propose that previously infected bone might be a risk for reinfection. Persistent symptoms or signs lasting longer than 10 days are consistent with chronic osteomyelitis and the development of necrotic bone. Draining sinus tracts often develop from the bone to the skin with chronic osteomyelitis.[1],[18]

J.F. probably experienced a chronic bone infection after the farming accident. The reappearance of sinus tract drainage in his left upper arm indicates an indolent infection of bone that was periodically suppressed, but not completely treated by oral antibiotics. Cultures of sinus drainage now reveal multiple organisms including normal skin flora. These sinus tract cultures usually do not correlate with the organisms actually causing bone infection. J.F.'s recurrent course of bone involvement with drainage and local symptoms, and lack of any remarkable systemic symptoms, suggests chronic osteomyelitis.[18]

SURGERY AND ORAL ANTIBIOTICS

CASE 73-4, QUESTION 2: Oral levofloxacin (500 mg daily) was restarted 2 weeks ago when J.F.'s left arm became more painful and drainage increased. Was his poor response to therapy unexpected? How should his case have been managed?

J.F.'s poor response should have been expected for at least two reasons: Antibiotic therapy was started before surgical debridement of avascular tissue, and he was given an antibiotic that was inactive against the cultured bone organisms.

Surgery plays an important role in the treatment of chronic osteomyelitis. Bone necrosis will continue to progress if decompression and drainage of the infected area is not carried out as soon as possible. Furthermore, without initial surgical removal of necrotic bone (sequestrum) and other poorly vascularized, infected material, even the most optimal IV antibiotics are likely to fail.

After surgery, antibiotic therapy directed against the pathogens isolated in the surgical specimens should be started. The regimen choice should not be based on the sinus tract culture results because these isolates may not correlate with the actual causative organisms. J.F. should be treated initially with IV antibiotics because of relatively poor blood flow at the infection site. Although the optimal duration of therapy for chronic osteomyelitis is not well established, the standard recommendation has been parenteral therapy for 6 weeks, followed by oral antibiotic therapy, depending on the healing rate.[19] However, based on more recent data with oral antibiotics in chronic osteomyelitis, the susceptibility of the antibiotic for the organism is more relevant than the route of administration.[19],[20] J.F. should continue to be evaluated by an orthopedic surgeon because he may require further surgical treatment to eradicate chronically infected bone.

INTRAVENOUS ANTIBIOTICS

CASE 73-4, QUESTION 3: What would be reasonable antibiotic therapy for J.F.?

On the basis of the bone culture and sensitivity results, J.F. needs high-dose therapy directed at P. mirabilis and B. fragilis. For convenience and possible future home therapy, ceftriaxone (2 g IV every 24 hours) could be started for coverage of Proteus and metronidazole (500 mg IV every 8 hours) also should be started for coverage of B. fragilis. Because of excellent oral bioavailability, the metronidazole can be rapidly converted to oral therapy at the same dose before discharge. Ertapenem could be an alternative choice for home IV therapy assuming that the Proteus isolate is sensitive. This agent also provides excellent anaerobic activity, and its once-daily dosing (1 g IV every 24 hours) is convenient for home therapy.

After 6 to 8 weeks of home parenteral therapy, J.F. should be evaluated for response. If symptoms have abated, treatment with oral antibiotics (trimethoprim-sulfamethoxazole and metronidazole) may commence and should continue for an additional 6 to 8 weeks or longer depending on resolution of the sinus tract drainage, pain, and tenderness in J.F.'s arm. Under these circumstances, he should be monitored closely for possible long-term adverse drug effects (e.g., hepatitis, cytopenias, neuropathy). If the sinus tract does not heal or if J.F. remains symptomatic, surgical exploration and bone cultures must be repeated.

LOCAL ANTIBIOTICS

CASE 73-4, QUESTION 4: What is the rationale for and effectiveness of local antibiotic administration (the PMMA beads) inserted during J.F.'s orthopedic surgery?

To deliver high concentrations of antibiotics to poorly vascularized bone infection sites, various materials containing antibiotics can be placed at the infection site during surgery. Plaster pellets, fibrin, collagen, hydroxyapatite, and PMMA impregnated with antibiotic, usually an aminoglycoside or vancomycin, have been used. The dosage form is designed for the slow release of antibiotics from the material. The most commonly reported experience with local antibiotic delivery has been with antibiotic-impregnated PMMA cement or beads inserted during joint arthroplasty. Local delivery of antibiotics should not replace systemic antibiotics in the treatment of chronic osteomyelitis.[21]

Osteomyelitis Associated with Prosthetic Material

USUAL CLINICAL PRESENTATION

CASE 73-5

QUESTION 1: A.T., a 47-year-old woman, had a left knee replacement 1 year ago for osteoarthritis. She is seen today in the orthopedic clinic because of increasing left knee pain for the past 2 months. The knee is painful and warm. She is afebrile, and her peripheral WBC count is 9,800/μL. Aspiration of fluid from the knee reveals a total nucleated cell count of 78,000/μL with 90% neutrophils. A Gram stain of this fluid shows 4+ polymorphonuclear leukocytes (PMN) and 1+ gram-positive cocci. She is started on antibiotic therapy with vancomycin and ciprofloxacin pending culture results, and she is scheduled for operative evaluation and possible removal of her prosthetic joint. Does A.T. have a prosthetic joint infection?

Joint replacement surgery is commonly performed for patients with significant joint destruction as a result of arthritis and other disabling diseases. Prosthetic knee, shoulder, elbow,

---

or hip devices made of metallic alloys are cemented to adjacent bone to re-establish joint function. Infection of these foreign bodies can occur because of exogenous inoculation of bacteria perioperatively, via hematogenous dissemination of bacteria, or by contiguous spread from a topical wound. Bacteria infect bone adjacent to the joint prosthesis, including the bone–cement interface, resulting in a loosened and less functional prosthesis.[22] Staphylococcus species including coagulase-negative species such as S. epidermidis are most commonly involved in prosthetic joint infections, followed by Streptococcus species, gram-negative bacilli, and anaerobes. Although coagulase-negative staphylococci are usually considered a contaminant in culture, this organism readily adheres to prosthetic material and should be considered pathogenic when cultured from prostheses. Coagulase-negative staphylococci are often methicillin-resistant but susceptible to vancomycin.

Chronic pain, swelling, erythema, and tenderness over a prosthetic joint are typical findings associated with prosthetic joint infection. Persistent wound drainage may also be present. A.T. has had a relatively lengthy duration of symptoms associated with her left knee, which could be caused by joint loosening, but the cell count and differential from the joint aspirate suggest joint infection. Consistent with infected prosthesis is also the predominance of neutrophils in her joint fluid and gram-positive cocci on a Gram stain. As is often the case, she has no obvious preceding source of infection from which bacteria may have originated. Occasionally, sources of infection with hematogenous dissemination to the prosthetic joint are identified, such as dental infections, cellulitis, or urinary tract infections. Given the Gram stain result, A.T. should receive coverage for Staphylococcus and Streptococcus species with vancomycin while awaiting the results of cultures and sensitivities. Because gram-negative bacteria also can infect these joints, gram-negative coverage is reasonable until the results of joint fluid cultures are available.

SURGERY

CASE 73-5, QUESTION 2: Does A.T. need surgery and antibiotics to cure her infection?

Surgical removal of A.T.'s knee prosthesis in conjunction with intravenous antibiotics for 6 weeks is the current recommendation for optimal eradication of prosthetic joint infection.[22],[23] A two-stage orthopedic procedure is frequently used that involves removal of the infected prosthesis, placement of an antibiotic-filled spacer, joint immobilization, and antibiotics for 6 weeks. If the joint space remains culture negative after 2 weeks of antibiotics, a new joint prosthesis is then reinserted. Because avascular bone cement and prosthetic material can become seeded with bacteria, complete removal of this material is necessary to have the greatest chance of curing the infection. Six weeks of systemic antibiotic therapy in combination with orthopedic surgery results in restoration of joint function in 80% to 90% of cases. High rates of treatment failure occur if the joint prosthesis is not removed, if the antibiotic duration is too short, and if chronic suppressive antibiotics are not given.[22],[23]

ANTIBIOTICS

CASE 73-5, QUESTION 3: The surgeon is unable to completely remove A.T.'s prosthetic joint. The removed lining material and three swabs of the left knee prosthesis grow MRSA. What antibiotic regimen could be used? How long should A.T. be treated?

Because A.T.'s prosthesis cannot be removed, she will need 2 to 6 weeks of vancomycin (15 mg/kg IV Q12 hours) plus oral rifampin (300–450 mg PO BID), followed by 6 months of oral antibiotics plus rifampin.[23] Daptomycin (6–10 mg/kg IV daily) or linezolid (600 mg PO/IV Q12 hours) may be considered alternatives to vancomycin, depending on pathogen susceptibility, drug allergies or intolerances, and potential drug–drug interactions.[23],[24] However, these agents are not FDA-approved for prosthetic joint infections, and they require monitoring for adverse effects, such as creatine kinase elevations (daptomycin) and bone marrow suppression and neuropathy (linezolid).[22] Combination therapy with rifampin should be used for prosthetic joint infection caused by staphylococci, particularly if removal of the infected prosthesis is not possible, because rifampin penetrates bacterial membranes and biofilms to enhance the bactericidal activity of the antibiotic regimen. Monotherapy with rifampin should never be used because of rapid development of resistance.[25],[26] Rifampin induces the metabolism of multiple other agents (e.g., warfarin, anticonvulsants, azole antifungals); therefore, a thorough review of A.T.'s medication profile is critical. A.T.'s baseline liver function should also be evaluated and rechecked at least monthly while she is taking rifampin.[27]Additionally, weekly assessment of A.T.'s complete blood count and renal function along with periodic vancomycin trough serum concentrations should be performed.[28]

SEPTIC ARTHRITIS

Septic arthritis or infectious arthritis is usually acquired hematogenously. The highly vascular synovium of the joint allows easy passage of bacteria from blood into the synovial space. Bacteremia, secondary to Neisseria gonorrhoeae or S. aureus in particular, often is associated with joint infections. Septic arthritis also can develop secondary to inoculation of pathogens due to trauma, including puncture (e.g., animal bites, nail) or surgery, as well as via contiguous spread from osteomyelitis.[29]

Several factors predispose patients to the development of infectious arthritis. Patients with abnormal joint structure, including rheumatoid arthritis (RA), prosthetic joints, or recent joint surgery, are more susceptible to the development of infection. Patients with age greater than 80 years, diabetes mellitus, and chronic illnesses such as malignancy and chronic renal failure are also at an increased risk. Gonococcal arthritis may occur in those who have been exposed to or are infected with N. gonorrhoeae.[29]

Clinical Presentation of Nongonococcal Arthritis

CASE 73-6

QUESTION 1: C.H., a 45-year-old man, is referred to the rheumatology clinic for left knee swelling. Two days ago, his left knee became painful and swollen, and he is unable to flex the joint. He also recorded temperatures at home of 100.7°F to 102°F for at least 4 days. In clinic, a joint effusion is noted, and fluid is aspirated for cell count, Gram stain, and culture. His medical history is unremarkable. C.H.'s WBC count is 16,000/μL, and his ESR is 42 mm/hour. The synovial fluid from his right knee contains 30,000 WBC/μL with 90% neutrophils, and the Gram stain shows gram-positive cocci in clusters. Culture results are pending. His temperature is 38.5°C. What findings in C.H. are consistent with septic arthritis?

C.H. has an acute onset of monoarticular joint pain and swelling, with reduced range of motion and fever. These findings are classic for septic, nongonococcal arthritis. The joint effusion shows a predominance of neutrophils, which confirms the diagnosis. C.H.'s knee has been infected hematogenously from a distant, unrecognized, source of infection. The knee is infected

---

most frequently, and the most common causative pathogens are Gram-positive, including Staphylococcus, Streptococcus, and Enterococcus species.

A single joint is infected in 80% to 90% of nongonococcal arthritis cases. Other possible sites of infectious arthritis in adults besides the knee include the hip, shoulder, sternoclavicular, sacroiliac, and ankle joints.[29] Patients commonly present with fever, pain, swelling, redness, and decreased mobility of the involved joint.

As illustrated by C.H., most patients have joint effusion on physical examination.

When evaluating a patient with possible septic arthritis, any purulent joint effusion should be considered septic until proven otherwise. Alternatively, noninfectious conditions may be present, such as single joint involvement with synovial effusions in acute RA, gout, or chondrocalcinosis.[29]

Aspirated joint fluid should be cultured because isolation of bacteria is the only definitive diagnostic test for bacterial arthritis. C.H.'s joint fluid picture is typical. The leukocyte count in the synovial fluid usually is elevated significantly, with counts above 50,000/μL with a predominance of neutrophils (>75%). Blood cultures are positive in 25% to 70% of patients.

Another laboratory finding in C.H. consistent with infectious arthritis is the elevated ESR and peripheral WBC count. CRP is frequently elevated as well, although both ESR and CRP are nonspecific markers of inflammation and can be elevated due to causes other than infectious arthritis.

The patient's age impacts the most common bacterial cause of infection. In adults older than 30 years of age such as C.H., and in children older than 2 years of age, S. aureus is the most common bacterial source. In sexually active young adults, N. gonorrhoeae is more likely to be the causative agent. Streptococci, such as group A β-hemolytic streptococci, can cause infection in children and adults. Other organisms, such as group B streptococci, anaerobic streptococci, and gram-negative bacteria, can also cause infection. Gram-negative bacilli are responsible for approximately 5% to 20% of cases and often infect multiple joints. Infections with gram-negative bacteria usually are associated with predisposing factors, such as RA, osteoarthritis, history of joint surgery, intra-articular injections, or intravenous drug use. An organism commonly isolated from patients with bacterial arthritis who have a history of IV drug use is P. aeruginosa.[29],[30]

Initial Antimicrobial Therapy

CASE 73-6, QUESTION 2: How should C.H. be treated, and for how long? How should the efficacy of treatment be monitored?

Treatment of nongonococcal arthritis includes drainage of purulent joint fluid (by needle aspiration or surgery) and appropriate antibiotic therapy. Because of the increasing frequency of community-acquired MRSA causing infection, initial empiric therapy with vancomycin (15 mg/kg/dose IV every 12 hours, goal serum trough concentration 15–20 mg/L) should be initiated to provide coverage for this and streptococci in C.H. Daptomycin and linezolid are typically reserved for patients with vancomycin intermediate-susceptible or resistant gram-positive organisms or those patients with intolerance or allergy to vancomycin. Vancomycin can be changed on the basis of sensitivity testing to oxacillin, nafcillin, or cefazolin if the isolated organism is susceptible.[29],[30]

DURATION OF THERAPY

No high-quality studies have been performed to determine the optimal duration of therapy for bacterial arthritis.[30] Previous recommendations based on early clinical trials recommended treating for 2 to 3 weeks.[31] However, current recommendations are to initiate therapy with at least 2 weeks of IV antibiotics, followed by oral antibiotics (if possible based on susceptibilities) for at least 4 more weeks.[29],[30]

C.H. should be treated for at least 4 weeks.[29],[30] His response to therapy should be monitored clinically (resolution of symptoms, fever, and falling ESR, CRP, or both) as well as by periodic evaluation of joint fluid. Frequent aspirations of joint fluid via closed-needle aspiration or following arthroscopic lavage, and debridement and insertion of drains will permit daily evaluation of cell count and fluid culture. Effective therapy should result in a decreasing WBC count in the joint fluid and negative cultures, usually within 3 to 4 days of treatment.[29]

Joint inflammation and other symptoms also should diminish during the first week of treatment. The duration of articular symptoms before antibiotic therapy begun correlates with the subsequent time required to sterilize the synovial fluid. Therefore, delay in initiating antibiotic treatment may necessitate a longer course of therapy.

Similar to hematogenous osteomyelitis, oral antibiotics have been used in septic arthritis to complete treatment if the initial response to IV therapy is adequate for some pathogens and in patients at lower risk for recurrent infection.[29],[30] C.H. should be advised that parenteral treatment with vancomycin, which can be accomplished at home, would be the most effective mode of treatment if his cultures grow MRSA, because this pathogen typically requires 4 weeks of IV antibiotics. Finally, injections of antibiotics into the joint space are of no value. Most systemic antibiotics readily penetrate the joint space and enter the synovial fluid.

Gonococcal Arthritis

Polyarticular arthritis in a young, sexually active adult is caused most commonly by N. gonorrhoeae. Arthritis in multiple joints is a common feature of disseminated gonococcal infection (DGI). Unlike nongonococcal arthritis, which is almost exclusively monoarticular, gonococcal arthritis involves multiple joints in approximately 50% of cases. Women have a four-fold increased risk of developing gonococcal arthritis as compared with men, often due to delays in diagnosis of genital infection.[29],[32] Clinically, patients present with a migratory polyarthralgia often with fever, dermatitis, and tenosynovitis. Skin lesions are an important clue to the diagnosis of DGI and often begin as tiny erythematous papules and develop into larger vesicles. As in hematogenously acquired nongonococcal arthritis, the synovial fluid leukocyte count usually is elevated, but often to a lesser degree. N. gonorrhoeae is recovered in approximately 50% of purulent joint effusions, but is detected using polymerase chain reaction (PCR) assays that have approximately 96% specificity and 80% sensitivity. These laboratory studies, coupled with the patient's clinical presentation, can be used to make a definitive diagnosis.[29],[32]

CLINICAL PRESENTATION OF GONOCOCCAL ARTHRITIS

CASE 73-7

QUESTION 1: E.D, a 21-year-old woman, presents to the walk-in clinic with right knee and right shoulder pain, nausea, and vomiting. On physical examination, her right knee is swollen and she has decreased range of motion of her right shoulder. Several erythematous, papular skin lesions are noted on both hands. She also has a vaginal discharge. Her temperature is 38.2°C, and her WBC count is 15,000/μL. She gives a history of having two recent sexual partners. Cultures of blood, joint fluid, and vaginal discharge are obtained; a joint fluid Gram stain shows 4+ PMNs, but no organisms are seen. Why is E.D. considered to have gonococcal arthritis?

E.D. has systemic signs of infection (fever, nausea, vomiting, leukocytosis), skin lesions, and multiple joint involvement, which are classic for DGI. Her history of recent sexual activity and the presence of a vaginal discharge are consistent with gonococcal infection, although evidence of mucosal infection with N. gonorrhoeae is not necessary for disseminated infection to occur.[29],[32]

PATIENT WORKUP AND TREATMENT IN THE CLINIC

CASE 73-7, QUESTION 2: What additional workup should be done in E.D.? Can she be treated immediately in the clinic?

E.D. should be evaluated for other sexually transmitted diseases, specifically syphilis and HIV infection. Serologic testing for syphilis (rapid plasma reagent [RPR] or venereal disease research laboratory [VDRL] testing) and for antibody to HIV should be obtained. In addition, she should have a pregnancy test because some of the antibiotics that may be used are contraindicated during pregnancy, including doxycycline.

Because of possible penicillinase production by N. gonorrhoeae, recommended therapy is with ceftriaxone (1 g intramuscularly or IV every 24 hours) for at least 7 days. E.D. should receive her first dose of ceftriaxone in the clinic today. Conversion to oral antibiotics should be guided by antimicrobial susceptibility testing following 24 to 48 hours of clinical improvement by the patient.[33]

E.D.'s sexual partners should also be evaluated and treated for relevant sexually transmitted diseases. She should also be counseled on utilization of barrier methods (e.g., condoms) to prevent sexually transmitted infections.

FULL COURSE OF THERAPY

CASE 73-7, QUESTION 3: Results of RPR and pregnancy testing in E.D. are negative. How should she complete her course of therapy?

E.D.'s DGI should be treated for at least 7 days. E.D. also should begin treatment with azithromycin (1 g orally once) or doxycycline (100 mg orally twice daily for 7 days) for the possibility of concomitant chlamydial infection. Azithromycin is preferred because of increasing resistance with tetracyclines.[34] Treatment guidelines for DGI are also included in the gonorrhea section of Chapter 72, Sexually Transmitted Diseases.

CORE PRINCIPLES

	CHAPTER CASES
SKIN AND SOFT TISSUE INFECTIONS	
① Cellulitis (an acute inflammation of the skin and subcutaneous fat) is characterized by local tenderness, pain, swelling, warmth, and erythema with or without a definite entry point.	**Case 74-1 (Question 1)**
② Cellulitis is most often caused by group A β-hemolytic streptococci (Streptococcus pyogenes) and, less often, Staphylococcus aureus.	**Case 74-1 (Question 1), Table 74-1**
③ Community-acquired methicillin-resistant S. aureus (CA-MRSA) may be a causative pathogen, especially in high-risk patients (children, competitive athletes, prisoners, soldiers, selected ethnic populations, Native Americans/Alaska Natives, Pacific Islanders, intravenous drug users, men who have sex with men), and empiric treatment should have activity against CA-MRSA.	**Case 74-1 (Question 1)**
④ For most cases of cellulitis requiring antibiotics, the least expensive of dicloxacillin or cephalexin should be chosen. Cases of cellulitis as evidenced by signs of systemic infection require parenteral antibiotics. The duration of therapy should be at least 5 days.	**Case 74-1 (Questions 1, 4) Case 74-2 (Question 1)**
⑤ Conversion to oral antibiotic therapy should be considered when patients show signs of clinical improvement and are afebrile for at least 24 hours.	**Case 74-2 (Questions 3, 4)**
⑥ Abscesses, furuncles, and carbuncles are commonly caused by S. aureus and should be managed with incision and drainage. Antibiotic therapy is warranted when systemic inflammatory response syndrome is present.	**Case 74-3 (Questions 2, 3), Table 74-1**
ERYSIPELAS	
① Oral or parenteral penicillins, with activity against group A streptococci, are the drugs of choice for treatment.	**Case 74-4 (Question 1), Table 74-1**
SKIN AND SOFT TISSUE INFECTIONS IN DIABETIC PATIENTS	
① Skin and soft tissue infections are very common in diabetic patients with	**Case 74-5 (Question 1)**

	approximately 25% of patients reporting a history of skin and soft tissue infection.	
②	Mild infections in diabetics can be treated similar to cellulitis (Gram-positive coverage), whereas moderate-to-severe infections require broad-spectrum coverage.	**Case 74-5 (Questions 1, 2)** **Table 74-1**

NECROTIZING SOFT TISSUE INFECTIONS

①	Necrotizing soft tissue infections can progress rapidly to cause local (e.g., necrosis and loss of skin sensation) and severe systemic effects (e.g., hypotension, shock).	**Case 74-6 (Question 1)**
②	Initial treatment of necrotizing soft tissue infections involves extensive debridement to remove all necrotic tissue, fluid resuscitation, and broad-spectrum antibiotics.	**Case 74-6 (Question 1),** **Table 74-1**

ANIMAL BITES

①	The oral flora of animals (cats, dogs) necessitates irrigation to reduce risk of infection and may include aerobic or anaerobic organisms. Amoxicillin/clavulanate is the preferred first-line agent.	**Case 74-7 (Questions 1, 2)** **Table 74-1**

HUMAN BITES

①	Treating a human bite is similar to any other laceration, including cleansing, irrigating, exploring, debriding, draining, excising, and suturing, as required. Human-bite infections can be caused by aerobic and anaerobic organisms and should be treated with amoxicillin/clavulanate or ampicillin/sulbactam, or ertapenem.	**Case 74-8 (Question 1),** **Table 74-1**

Skin and soft tissue infections may involve any or all layers of the skin (epidermis, dermis), subcutaneous fat, fascia, or muscle. Many terms or classifications are used to describe various skin and soft tissue infections, and these often are based on the site of infection and causative organism(s).[1] This chapter focuses on skin and soft tissue infections that are primarily the result of a break in the skin after an abrasion, skin puncture, ulceration, surgical wound, intentional or unintentional insertion of a foreign body, or blunt soft tissue contusion. Treatment of skin and soft tissue infections often is empiric and based on the severity and site of infection, presence of purulence, the patient's underlying immunocompetence, and the triggering event (e.g., abrasion, bite, insertion of a foreign object) because attempts to isolate the causative organism often are futile.

SKIN AND SOFT TISSUE INFECTIONS

Cellulitis (an acute inflammation of the skin and subcutaneous fat) is characterized by local tenderness, pain, swelling, warmth, and erythema with or without a definite entry point. Cellulitis is usually secondary to trauma or an underlying skin lesion that allows bacterial penetration into the skin and underlying tissues. Cellulitis is most often caused by group A β-hemolytic streptococci (Streptococcus pyogenes) and other streptococcus species (B, C, F, or G), and less often, Staphylococcus aureus (Table 74-1).[2] However, if the patient presents with abscess, purulence, or penetrating trauma, coverage of S. aureus is indicated.[2] Coverage for community-acquired methicillin-resistant S. aureus (CA-MRSA) may be warranted because the incidence has been increasing.[3] Gram-negative organisms (e.g., Escherichia coli, Pseudomonas aeruginosa, Klebsiella pneumoniae) also can cause cellulitis, but should be suspected only in immunocompromised patients or in patients who fail to respond to antibiotics that have activity limited to Gram-positive organisms. Wound cultures often are negative and fail to identify the causative organism.

Severity of infection is based upon presence of systemic signs of infection, failure of oral antibiotics, and immunocompetence. Cases of mild cellulitis without signs of systemic infection often require treatment with antibiotics active against streptococci. Patients with evidence of a systemic infection, suggesting a moderate-to-severe infection, will require intravenous [IV] antibiotics, in addition to local wound care. Severe infections occur in patients who have failed oral antibiotic therapy or those that are immunocompromised. Antibiotic selection is based on the suspected etiology as well as severity of infection.

In addition to cellulitis, skin and soft tissue infections include abscesses, furuncles, and carbuncles. A skin abscess is an infection and results in a collection of pus within the dermis and deep skin tissues.[2] Furuncles are abscesses that initiate in the hair follicle and penetrate into the surrounding subcutaneous tissue, whereas carbuncles are a coalescence of furuncles.

Table 74-1

Potential Organisms Causing Skin and Soft Tissue Infections

	Gram Positive		Gram Negative		Anaerobes		
	Staphylococcal	Streptococcal	Escherichia coli, Klebsiella species, Proteus Species	Pasteurella multocida	Eikenella corrodens	Oral Anaerobes	Clostr Specie
Cellulitis	X	X					
Diabetic soft tissue	X	X	X				

Necrotizing infections	X	X	X			X	X
Erysipelas		X					
Animal bites	X	X	X	X		X	
Human bites	X	X	X		X	X	

X, organisms that should be covered empirically with appropriate antibiotic therapy.

CASE 74-1

QUESTION 1: N.P., a 25-year-old woman, presents to her family doctor with a 2- to 3-day history of worsening pain, redness, and swelling on her left leg after an abrasion that occurred after falling while jogging in the park. The area is red, painful, nonpurulent, and warm to the touch. During the past 24 to 36 hours, the leg has become increasingly painful and “tight.” N.P. denies having fever or chills. The presumptive diagnosis is a mild cellulitis, and dicloxacillin is prescribed. Why is dicloxacillin appropriate empiric treatment for N.P.?

Oral dicloxacillin is appropriate empiric therapy for cellulitis in an otherwise healthy individual with no signs or symptoms of systemic infection, regardless of presence of purulence. Dicloxacillin has predictable activity against streptococcus and methicillin-sensitive staphylococcus organisms and is better tolerated than erythromycin or clindamycin. Because the patient presents with nonpurulent cellulitis, penicillin VK is also an option; however, it lacks coverage against staphylococcus. If the cellulitis is well demarcated and nonpurulent, penicillin alone can be appropriate because the causative organism is likely to be Streptococcus. Many other available antibiotics that have activity against staphylococcus and streptococcus organisms have been evaluated for effectiveness in skin and soft tissue infections. A recent review concluded that the available evidence does not allow specific recommendations for the best antibiotic regimen for cellulitis.[3],[4] Cephalexin is probably as effective and as well tolerated as dicloxacillin and is comparable in cost. However, the Gram-negative activity of cephalexin (not present with dicloxacillin) is not required for most cases of cellulitis in otherwise healthy patients. In this case, antibiotic treatment is required, and N.P. can receive dicloxacillin or cephalexin.

In geographic areas where the incidence of CA-MRSA has become clinically important (>10% of isolates), particularly with additional risk factors (children, competitive athletes, prisoners, soldiers, selected ethnic populations, Native Americans/Alaska Natives, Pacific Islanders, IV drug users, men who have sex with men), empiric treatment should include antibiotics with activity against CA-MRSA.[5] In cases in which there is an abscess without signs of systemic infection, drainage is often all that is needed because antibiotic therapy has been shown to be no better than placebo for uncomplicated skin abscesses in a population at risk for CA-MRSA infection.[6] At present, most CA-MRSA are still susceptible to trimethoprim-sulfamethoxazole, clindamycin, and doxycycline.[2] Although trimethoprim-sulfamethoxazole has good activity against S. aureus, its activity against S. pyogenes, that is group A streptococci, is weak, making this antibiotic undesirable alone as empiric therapy. If these agents are used, a reasonable suggestion would be to re-evaluate (by the patient if they are competent) within 24 to 48 hours to verify that an improvement is occurring. Some clinicians avoid the use of clindamycin because of concerns of inducible resistance. In areas with a clinically important incidence of CA-MRSA, laboratories should test for inducible clindamycin resistance. If N.P. is from an area of high CA-MRSA prevalence and has associated risk factors, the combination of trimethoprim-sulfamethoxazole or doxycycline with beta-lactam (penicillin, cephalexin, amoxicillin) would provide therapy for the anticipated pathogens. However, even in areas of high CA-MRSA prevalence, some investigations have found cephalexin to be as effective as therapy specifically targeted for CA-MRSA, although this has not been supported in all studies.[7–9] If CA-MRSA does not require antibacterial coverage, this practice may reduce antibacterial selection pressure and expense.[10]

CASE 74-1, QUESTION 2: What agents could be chosen if N.P. is allergic to penicillin?

Clindamycin could be chosen for patients with a documented history of penicillin or cephalosporin allergy.[2] In certain geographic areas, group A streptococci macrolide resistance approaches 15% to 20%, decreasing the potential value of this agent. Clindamycin is superior to macrolides with respect to group A streptococcal coverage; however, it causes diarrhea in 20% of patients and is one of the main agents responsible for antibiotic-associated colitis. Moxifloxacin and levofloxacin are potential alternatives that have the convenience of once-daily dosing.

CASE 74-1, QUESTION 3: What dose should be prescribed for N.P.?

The recommended dosage of dicloxacillin is 500 mg orally every 6 hours. The dosage for penicillin V is 250 to 500 mg orally every 6 hours; for oral clindamycin, the dosage is 300 to 450 mg every 6 hours. Because dicloxacillin is the drug chosen for N.P., a dosage of 500 mg orally every 6 hours is appropriate. The dose for doxycycline is 100 mg orally every 12 hours, and the dose for trimethoprim-sulfamethoxazole is one to two double-strength tablets orally every 12 hours. The recommended dose for moxifloxacin is 400 mg orally every 24 hours and 500 mg orally every 24 hours for levofloxacin.

CASE 74-1, QUESTION 4: What is the appropriate duration of therapy for N.P.?

Although the recommended duration of therapy for cellulitis is 5 days, treatment may be extended if clinical improvement is not seen.[2] A reasonable recommendation to the patient would be to continue oral antibiotics for 2 to 3 days after the patient has become afebrile and has clinically improved. N.P. should be counseled to expect a response within 1 to 2 days after therapy begins (although erythema may persist longer). In addition, she should be instructed to return for re-evaluation if the condition does not improve or worsens during the next few days.

CASE 74-1, QUESTION 5: What further diagnostic evaluation should be undertaken for N.P.?

In otherwise healthy individuals, identification of the causative organism in cases of mild cellulitis is unnecessary. Needle aspiration, fine-needle aspiration biopsy, and punch biopsy identify the causative organism in only 20% to 30% of patients.[2] Appropriate empiric treatment is effective in most patients, and an attempt to isolate the organism does not improve success of treatment and adds significantly to the cost of care. However, patients with moderate-to-severe purulent infection, patients who failed initial empiric therapy, immunocompromised patients, patients with potential joint or tendon damage, or patients with life-threatening infections requiring hospitalization may benefit from additional cultures. In these cases, a swab of the primary wound and a needle aspiration or punch biopsy of the leading edge of the cellulitis should be obtained for Gram stain and culture before initiating antimicrobial therapy. Blood and wound cultures should be drawn in these patients. Anaerobic cultures need to be drawn only when the wound contains necrotic tissue, the wound is foul smelling, or crepitus is present. Even if wound and blood cultures are obtained, many infections will be culture negative (74%). Blood culture results are positive in less than 5% of cellulitis cases. Culture information, in conjunction with clinical course, can be used to modify subsequent treatment. Because N.P. has only a mild cellulitis, cultures are not required and therapy should be given empirically. In addition to systemic therapy, N.P. should be instructed to keep the area clean

---

with soap and water (if an open wound is present) and to protect the area. Treatment of cellulitis should also include rest, immobilization and elevation of the infected area, and surgical drainage or debridement, as required. The wound should be assessed daily for local tenderness, pain, erythema, swelling, ulceration, necrosis, and wound drainage.

CASE 74-1, QUESTION 6: Could topical antibiotics be used to treat N.P.'s cellulitis?

The value of topical antibiotics in treating skin infections is questionable.[11] Most topical antibiotics have not been evaluated in appropriately designed trials. Although mupirocin is superior to placebo in treating some types of wound infections, its value in more severe disease is uncertain. In patients with moderate-to-severe infections, mupirocin, or any topical antibiotics (neomycin, bacitracin, polymyxin B) should not be used to replace or augment systemic antibiotics. Topical antibiotics likely do little but add to the cost of therapy, and they occasionally cause a contact dermatitis. Therefore, N.P. should not be treated with topical antibiotics because her cellulitis should be managed adequately by her systemic antimicrobial therapy.

CASE 74-2

QUESTION 1: O.A., a 49-year-old man, presents to the ED with a 3- to 4-day history of increasing pain around his left hip, secondary to an injury he received falling on the sidewalk. In addition, he has a fever and feels weak, lethargic, and nauseated. Examination reveals a swollen, warm, and extremely tender hip. O.A. has a temperature of 39.8°C and appears quite ill. A diagnosis of moderate-to-severe cellulitis is made, and O.A. is hospitalized because of the severity of the infection. O.A. has no other underlying medical problems. What empiric antibiotic regimen would be reasonable for O.A.?

In moderate-to-severe ill patients, when hospitalization is required, antibiotics should be administered parenterally. The parenteral agent of choice is nafcillin or oxacillin.[2] Cefazolin (1–2 g IV every 8 hours) would be an appropriate alternative if it is less expensive than nafcillin. Second- and third-generation cephalosporins (cefuroxime, cefoxitin, ceftriaxone, cefotaxime) and some quinolones may be as effective as nafcillin, but provide no clinical advantages for most cellulitis. Patients with risk factors for MRSA (penetrating trauma, history of MRSA, nasal colonization, IV drug abuse, presence of systemic inflammatory response syndrome) should be treated with vancomycin or agents with activity against Streptococci and MRSA. One potential option is linezolid, but is limited by potential for drug interactions with serotonergic agents. Other agents include daptomycin, telavancin, dalbavancin, oritavancin, and ceftaroline. Although these agents are as effective in severe cellulitis, they are not used as commonly as vancomycin because of cost and formulary availability.

Therefore, O.A. should receive either nafcillin, oxacillin, or cefazolin, whichever is less expensive and more tolerable for the patient. Once O.A. has become afebrile and has evidence of clinical improvement, the parenteral antibiotic should be discontinued and appropriate oral therapy should be initiated to complete at least a 5-day course (or until clinical improvement).

CASE 74-2, QUESTION 2: Two days after starting therapy, O.A. develops a maculopapular skin rash. What alternative therapy should be chosen?

Regardless of when during the course of therapy a drug rash occurs (early or late), the precipitant drug should be discontinued because there is a chance, although small, that the reaction could worsen. In patients who have a penicillin allergy and who still require parenteral therapy, clindamycin, vancomycin, linezolid, moxifloxacin, or levofloxacin could be chosen. Because all of these agents are equally effective, the choice should be based on cost and dosing convenience and presence of risk factors for MRSA.

CASE 74-2, QUESTION 3: After 48 hours of therapy, culture and sensitivity results are available. What changes, if any, should be made in O.A.'s treatment?

If cultures show only streptococcus species in a patient who is not allergic to penicillin, therapy should be deescalated to penicillin because it is effective, well tolerated, and less expensive than nafcillin. If cultures grow staphylococcus species (S. aureus) that are sensitive to methicillin/oxacillin, the initial empiric therapy should be continued. If the organisms are resistant to methicillin/oxacillin, therapy should be switched to vancomycin 15 mg/kg IV every 12 hours or alternative agent as previously described. Because O.A. has a presumed penicillin allergy (due to maculopapular rash) and does not require therapy for MRSA, he should continue with clindamycin or vancomycin. Cefazolin may also be an option for penicillin-allergic patients who do not experience severe allergic reactions, such as urticaria and anaphylaxis.

CASE 74-2, QUESTION 4: After 72 hours of therapy, O.A. has improved considerably and has been afebrile for 24 hours. Can he be switched to oral therapy?

Once O.A. has been afebrile for at least 24 hours and is significantly improved, he can be switched to oral therapy, if tolerated. Clinicians should select the oral agent on the basis of culture results (if available), anticipated pathogens (if no culture results), convenience, and cost.

CASE 74-2, QUESTION 5: What is the role of anti-inflammatory agents as adjunctive treatment of cellulitis?

Anti-inflammatory agents, such as nonsteroidal anti-inflammatory agents and corticosteroids, have been shown to decrease time to resolution of cellulitis when given in conjunction with antibiotics to patients without diabetes.[2] Although supporting evidence is weak, a significantly quicker resolution of symptoms in patients on prednisolone 5 to 30 mg/day has been seen.[2],[12],[13]

CASE 74-3

QUESTION 1: M.C. is a 22-year-old college football player who presents to the ED with a 3- to 4-day history of pain in his left thigh. On examination, he has a swollen, erythematous, and purulent 2 × 3 cm abscess in the inner left thigh. The area is warm and tender to the touch. M.C. is afebrile with no signs of lymphangitis. What tests are needed to confirm the diagnosis?

In patients with abscesses, large furuncles (superficial skin abscess), and carbuncles (clusters of furuncles), Gram stain and culture of pus is recommended.[2] Though, typically cases may be adequately treated without further testing. M.C. has risk factors for CA-MRSA (competitive athlete); if CA-MRSA is identified, infection control measures should be implemented to prevent outbreak.[14] In febrile patients, blood cultures should be drawn before antibiotics are started to maximize the ability to isolate the pathogen.

CASE 74-3, QUESTION 2: Are the suspected organisms similar to those found in other patients with cellulitis?

Abscess, furuncles, and carbuncles are most commonly caused by staphylococci, predominately S. aureus.[2],[6] Abscesses may also be polymicrobial. For patients who are IV drug abusers and present with abscess or cellulitis, the infecting bacteria are similar to those found in normal hosts. Intravenous drug use is also a risk factor for infection with CA-MRSA and should be particularly considered

---

if the patient has had recurrent infections or has failed to respond to MSSA-directed antibiotic therapy.[14] Although Staphylococcus epidermidis, Gram-negative organisms, including P. aeruginosa, and anaerobes are rarely pathogens, they may be present and should be considered in patients who do not respond to initial therapy.

CASE 74-3, QUESTION 3: What is the appropriate empiric therapy?

Antibiotic therapy is often not required. Incision and drainage should be performed for all abscesses, large furuncles, and carbuncles.[2] Antibiotics may be considered as adjunct to incision and drainage when systemic inflammatory response syndrome is present, but has not been shown to improve cure rates in patients with cutaneous abscess. Antibiotic therapy should be directed toward CA-MRSA and based on severity of infection. Mild-to-moderate infection can be adequately treated with doxycycline or sulfamethoxazole/trimethoprim, whereas more severe disease should be empirically treated with vancomycin, daptomycin, linezolid, telavancin, or ceftaroline.[2],[14] If treatment does not result in some resolution of inflammation within 48 hours, antimicrobial coverage should be expanded to cover Gram-negative organisms and resistant streptococci.

ERYSIPELAS

Erysipelas is a superficial skin infection caused by streptococci, predominantly group A, although groups C and G (and group B in children) also may cause the infection.[15],[16] This skin infection affects approximately 1 in 1,000 persons/year and is associated with diabetes mellitus, chronic venous insufficiency, and cardiovascular disease.[16] Erysipelas is diagnosed based on characteristics of the skin lesion and concurrent systemic symptoms.[15] The lesion is a continuous, indurated, edematous area, with a clearly defined raised edge.[16] Early in the course, the lesion is bright red, but it may turn to brown as the lesion ages or grows. The lesion spreads peripherally with no islands of unaffected tissue. The initial lesion results from a small break in the skin that becomes infected, although signs of the initial wound often are not evident. Aspiration of the lesion or a superficial swab is not recommended because this has not been shown useful in detecting the pathogen.[15] Patients with erysipelas have associated systemic symptoms of high fever, chills, frequent history of rigors, and general malaise. This constellation of systemic symptoms differentiates erysipelas from other local skin disorders.

CASE 74-4

QUESTION 1: D.D., a 70-year-old man, presents to the ED with a red, swollen face. He describes the area as "a swollen red spot" that has appeared during the past 2 days. He also describes feeling unwell for the previous 3 days and having a fever. On examination, D.D. has a bright red, shiny, edematous lesion on his right cheek that is 0.4 cm wide. It is a continuous lesion with a clearly demarcated border. What antibiotic therapy should be initiated for D.D.?

Erysipelas will respond promptly to antibiotics with activity against group A streptococci.[17] Oral penicillin V 250 to 500 mg every 6 hours and for severe cases and parenteral penicillin G (2–4 million units IV every 6 hours) generally reduce the systemic symptoms (e.g., fever, malaise) within 24 to 48 hours[17]; however, it will take several more days for the skin lesion to resolve. If D.D.'s condition does not improve within 72 hours after initiation of antibiotics, he should be instructed to return for reassessment. If D.D. has an allergy to penicillins, then a macrolide, clindamycin, or an oral fluoroquinolone, such as moxifloxacin, is an alternative.[15],[17] Ceftriaxone may also be an alternative in Penicillin allergic patients (without anaphylaxis) due to low (<1%) cross sensitivity risk. If the community has increased macrolide resistance to group A streptococci, these agents should not be part of empiric therapy. Antibiotic therapy should be continued for 10 days even if signs and symptoms resolve quickly to avoid a relapse, which could lead to chronic infection or scarring.

SKIN AND SOFT TISSUE INFECTIONS IN DIABETIC PATIENTS

Skin and soft tissue infections are common in patients with diabetes mellitus. Approximately 25% of diabetic patients report a history of skin and soft tissue infections, and 5% to 15% of diabetic patients may undergo limb amputation.[18] In addition to the cost associated with treating skin and soft tissue infections, functional disability may occur, which can significantly decrease the patient's quality of life. Diabetic patients are at particular risk for foot problems, primarily because of the neuropathies and peripheral vascular diseases associated with long-standing diabetes. The decreased pain sensation allows the patient to continue to bear weight in the presence of skin damage, thereby promoting the formation of an ulcer. In addition, minor trauma (e.g., cuts, foreign body insertion) can go unnoticed and, when left untreated, can become infected and extensive. Although these infections are common, preventive measures should reduce the frequency of amputations. Mild infections can be treated empirically with those agents used for soft tissue infections in nondiabetic patients because these are commonly caused by aerobic Gram-positive cocci. In moderate-to-severe infections, antibiotic coverage should be expanded because multiple organisms may be responsible for the infection. Although it is often difficult to determine colonizers from true pathogens, an average of two to six organisms are cultured from foot ulcers in patients with diabetes.[19],[20] The following organisms (in no particular order) have been isolated in more than 20% of wounds in patients with diabetes: S. aureus, S. epidermidis, Enterococcus faecalis, other streptococci, Proteus species, E. coli, Klebsiella species, Peptococcus species, Peptostreptococcus species, and Bacteroides species.[20] These infections are often polymicrobic, but treatment can be effective even if not all cultured pathogens are covered.[19] To determine the pathogens most accurately, a specimen of infected deep tissue should be obtained after the wound has been cleaned. If this is not possible, cultures of purulent exudate or curettage should be obtained, versus superficial swab, to determine the true pathogens in the wound.[18] Although antibiotics have an important role, drainage and surgical debridement to remove necrotic tissue are essential and may be the mainstay of treatment.[19] Cultures of the affected areas may not be useful unless bone is infected. Although anaerobic organisms often are difficult to culture, they must be considered if an abscess or devitalized, necrotic, foul-smelling tissue is present or the wound is a result of abdominal surgery.

CASE 74-5

QUESTION 1: T.U. is a 67-year-old man with diabetes presenting to his general practitioner for a routine checkup and has no specific complaints. T.U. has a 15-year history of poorly controlled type 2 diabetes and a 3-year history of recurrent foot ulcers. On examination, the physician observes that an ulcer on the underside of the foot, which had previously healed over, is open and inflamed; purulent fluid can be expressed from the wound. T.U. reports no pain around the area and was unaware that the ulcer had worsened. He is currently febrile, and physical examination reveals mild lymphadenopathy and elevated white blood cell count. Does T.U. have an active infection, and is antibiotic therapy required?

All open wounds, in diabetic and nondiabetic patients, will become colonized with bacteria, but only infected wounds should be treated with antibiotic therapy.[19],[20] Often it is difficult to determine whether an open wound is infected, but signs and symptoms (e.g., purulent drainage, erythema, pain, and swelling around the area) are suggestive of infection. Based on his symptoms, T.U. has an infection that requires treatment.

CASE 74-5, QUESTION 2: What treatment should T.U. receive?

Prior to initiating antibiotic therapy, the presence of a clinically infected wound must first be confirmed as often diabetic wounds may not be infected and thus do not require antimicrobial therapy. When determining appropriate antibiotic therapy for infected wounds, clinicians must consider the severity of infection (mild versus moderate to severe), whether the patient has risk factors for MRSA or P. aeruginosa or whether the patient has received any antibiotics within the past month. Mild diabetic foot infections should not be treated with topical antibiotic preparations because the evidence of efficacy is limited; the preparations do not allow sufficient penetration of antibiotic into the tissues; many preparations are detrimental to wound healing.[21] Mild infections can be treated empirically in a similar way to other soft tissue infections because these are commonly caused by aerobic Gram-positive cocci.[19] A penicillinase-resistant penicillin (e.g., dicloxacillin) or cephalexin will be effective in most cases. The choice between these agents should be based on tolerability and cost. Alternative agents include clindamycin, amoxicillin/clavulanate, or levofloxacin. If anaerobes are suspected (based on malodorous aroma, if the infection is severe or long-standing or has recently been treated with antibiotics), clindamycin or amoxicillin/clavulanate monotherapy can be used or metronidazole can be added to the regimen.[18] If metronidazole is selected, concurrent use of an antibiotic with good activity against aerobic pathogens is required, because metronidazole has no activity against aerobic bacteria. In patients with significant vascular compromise, crepitus, or gangrene, a radiograph should be taken to identify any bone involvement suggestive of osteomyelitis.

For treatment of moderate-to-severe infections, oral or parenteral antibiotics (IV recommended for severe) may be used depending on signs and symptoms and should be selected based on suspected organisms. For staphylococci, streptococci, and enterobacteriaceae, therapeutic options include levofloxacin, cefoxitin, ceftriaxone, ampicillin/sulbactam, moxifloxacin, ertapenem, and imipenem/cilastatin, or tigecycline.[20,21] Levofloxacin and ceftriaxone have no anaerobic coverage; thus, clindamycin or metronidazole should be added if anaerobes are suspected (ischemic or necrotic wounds).[22] It is important to consider that clindamycin may be more likely to cause Clostridium difficile-associated diarrhea.

Other considerations in antibiotic selection should include MRSA or P. aeruginosa when risk factors are present. Infections due to MRSA can be treated with vancomycin, daptomycin, or linezolid. Newer antibiotics, including dalbavancin, telavancin, oritavancin, and ceftaroline, have activity against MRSA skin and soft tissue infections, but there is a lack of efficacy data in diabetic foot infections.[23] Infections due to P. aeruginosa may be more common in patients in areas with high local prevalence, warmer climates, and frequent exposure of foot to water, and can be treated with piperacillin/tazobactam. Other antibiotics with activity against P. aeruginosa include, cefepime, ceftazidime, aztreonam, imipenem/cilastatin, meropenem, or doripenem. Aminoglycosides are associated with serious toxicity if used for an extended period and should probably be avoided in diabetic patients.

Because T.U. is an elderly diabetic patient with systemic signs and symptoms of infection (moderate to severe), empiric therapy with cefoxitin, ceftriaxone, ampicillin/sulbactam, levofloxacin, moxifloxacin, or ertapenem would be appropriate because he does not have risk factors for MRSA or P. aeruginosa infection.

CASE 74-5, QUESTION 3: Despite aggressive antibiotic therapy and debridement, T.U.'s infection spreads and an amputation is required. How long should antibiotics be prescribed for T.U. after surgery?

Antibiotics may be continued until signs and symptoms of infection have resolved. Typical treatment duration is 1 to 2 weeks; however, longer treatment duration (2–4 weeks) may be necessary in patients with moderate-to-severe infections or in patients with infections that are slow to resolve.[20] Oral therapy should be considered once the patient has clinically improved; treatment can be stopped even if the underlying ulcer has not completely healed.[18],[20]

The best option for uncontrollable, life-threatening infections often is amputation to remove the infected area. Once the infected area has been removed, antibiotic therapy should be continued for 2 to 5 days.[20]

CASE 74-5, QUESTION 4: What measures could have been taken to prevent this complication in T.U.?

Many of the foot problems associated with diabetes can be prevented with proper foot care (Table 74-2), and these preventive measures must be emphasized. Diabetic patients with neuropathies or those who are elderly should carefully examine their feet every 1 to 2 days.

Necrotizing Soft Tissue Infections

Skin and soft tissue infections are described as necrotizing when the inflammation is rapidly progressing and necrosis of the skin or underlying tissue is present. The following clinical signs suggest necrotizing infections, as opposed to simple cellulitis: edema beyond the area of erythema, skin blisters or bullae, localized pallor or discoloration, gas in the subcutaneous tissues (crepitus), and the absence of lymphangitis and lymphadenitis. Common clinical features include high temperature, disorientation, lethargy, or the hard wood feel of the infected area.[2] Occasionally, a broad erythematous track along the route of infection may also be present. Necrotizing soft tissue infections can progress rapidly to cause additional local effects (e.g., necrosis and loss of skin sensation) and severe systemic effects (e.g., hypotension, shock).[24] Necrotizing soft tissue infections are rare, with approximately 1,000 cases/year in the United States, but they can be lethal.[25],[26] Necrotizing infections can occur in healthy individuals, but are more commonly associated with IV or subcutaneous injections of illicit drugs.[27]

Table 74-2

Foot Care for the Diabetic Patient

Inspect feet daily for cuts, blisters, or scratches. Pay particular attention to the area between the toes and use a mirror to examine the bottom of the foot.
Wash feet daily in tepid water and dry thoroughly.
Apply lotion to feet to prevent calluses and cracking.
Ensure that shoes fit properly (not too tight or too loose) and inspect them daily.
Trim nails regularly, making sure to cut straight across the nail.
Do not use chemical agents to remove corns or calluses.

Necrotizing cellulitis involves the skin and subcutaneous tissues. Necrotizing fasciitis involves both superficial and deep fascia, and necrotizing infections involving the muscle are termed myonecrosis. Group A β-hemolytic streptococci, S. aureus, other staphylococci, Pseudomonas species, other Gram-negative organisms, Clostridium perfringens, Peptostreptococcus, B. fragilis, and Vibrio species can cause necrotizing infections.[24],[28] Gas gangrene is myonecrosis caused by a Clostridium subspecies, most commonly C. perfringens (70%).[24] Gas in a wound is not necessarily indicative of gas gangrene caused by C. perfringens. Gram-negative organisms (e.g., E. coli, Proteus species, Klebsiella species) or anaerobic streptococci can produce gas in a wound. Air also could have been introduced at the time of the injury. Gas gangrene is characterized by acute onset of worsening pain that is usually out of proportion to the degree of injury. Clostridial myonecrosis (true gas gangrene), streptococcal gangrene (caused by group A β-hemolytic streptococci), and synergistic bacterial gangrene (caused by anaerobic and aerobic bacteria, usually Gram negative) are other terms used to describe necrotizing skin and soft tissue infections. Fournier gangrene (a type of synergistic bacterial gangrene of the scrotum), nonclostridial crepitant gangrene (nonclostridial gas gangrene), and necrotizing fasciitis (all necrotizing soft tissue infections other than clostridial myonecrosis, or sometimes just streptococcal gangrene) are other commonly used terms.[24] The primary treatment for necrotizing soft tissue infections involves extensive debridement of the area to remove all necrotic tissue and drainage. Early fluid resuscitation and broad-spectrum antibiotics are also imperative.[25]

CASE 74-6

QUESTION 1: M.T., a 45-year-old alcoholic homeless man, presents to the ED with a broken nose and facial lacerations, which he received after a fight outside one of the local taverns. On examination, in addition to the facial wounds, an area of severe inflammation, erythema, and necrosis is evident on his left calf. The area is very painful, crepitation is felt over the area, and a purulent discharge is present. M.T. states he believes the infection is because of a knife wound he experienced approximately 1 week ago. What antibacterial treatment should be provided?

In addition to setting the broken nose and suturing the facial lacerations, the clinician should evaluate the infection on M.T.'s calf. A Gram stain and culture of the purulent discharge should take place before initiating antimicrobial therapy. Because crepitus is present, the area should be incised, and a specimen of the infected tissue should be obtained for Gram stain and culture. Because the presence of crepitus may suggest a necrotizing infection, an immediate surgical consultation will be required for M.T. Pending the surgical evaluation, fluid resuscitation and IV antibiotics should be initiated. Gas in the tissues could be caused by many organisms, and empiric broad-spectrum antibiotic therapy with coverage against Gram-positive organisms, the enterobacteriaceae, and B. fragilis should be started. Initial therapy with piperacillin/tazobactam, ampicillin/sulbactam, or a carbapenem plus anti-MRSA antibiotic (vancomycin, daptomycin, or linezolid) should be used.[2] Clindamycin is often added for suspicion of group A streptococci, not for its antibacterial effects but because it inhibits protein synthesis, which may reduce toxin expression by the bacteria, and cytokine response by the host.[2],[29] Alternative options include ceftriaxone plus metronidazole, or a fluoroquinolone plus metronidazole. If a Gram stain of the infected tissue clearly shows the predominance of Gram-positive cocci, consideration of narrowing the spectrum of antibiotic therapy is appropriate. Flesh-eating disease is usually a necrotizing fasciitis caused by virulent strains of group A streptococci. High-dose penicillin G (3 million units every 4 hours) plus clindamycin (900 mg IV every 8 hours) are the drugs of choice for this condition, as well as for gas clostridial myonecrosis.[2],[29]

Potential adjunctive therapy for streptococcal necrotizing skin infections includes IV immunoglobulin G (IVIG) 2 g/kg as a single dose or 0.4 g/kg daily for 2 days. Alternative dosage regimens have included 1 g/kg on day 1 with 0.5 g/kg on days 2 and 3.[30] No clinical trials have proven the definitive benefit of IVIG, and the optimal dose, if used, is unknown. If it truly provides benefit, IVIG is thought to work by binding to the superantigens released by the streptococcal bacteria that are involved in the systemic effects of the infection.[30],[31]

ANIMAL BITE WOUNDS

Any wound caused by an animal that results in the skin being cut or punctured should be examined to ensure no underlying tissue damage has occurred. This is especially true in patients with bites of the hand or around other joints. The wound should be washed thoroughly with clean water as soon as possible after the bite.[32] Irrigation of the wound, including puncture sites, should be extensive to reduce the risk of infection. Obtaining specimens for cultures is not required, and wound irrigation should begin as soon as possible.

Animal bites may develop bacterial infections due to aerobic or anaerobic organisms in up to 18% of cases.[33] Although purulent wounds or abscesses are likely to contain mixed aerobic and anaerobic organisms, nonpurulent wounds are more commonly caused by streptococci or staphylococci.[2] Pasteurella multocida is commonly isolated and is particularly significant in cat bites because it is present in up to 75% of the oral flora of cats.[2,33] Although antibiotic treatment is not required for some dog bites, reports of a greater than 75% incidence of infection after cat bites suggest that all patients with cat bites should receive antibiotics.[32]

CASE 74-7

QUESTION 1: P.J., a 18-year-old boy, presents to the ED 3 hours after being bitten on the leg by a neighbor's dog. He has a laceration, 14 cm long, on his medial calf. Four distinct puncture marks, suggestive of teeth marks, also are present on the calf. There is no suggestion of bone injury. P.J. was healthy before the attack and has no chronic illness. Should P.J. receive any treatment other than suturing of his laceration?

The standard of care for all bites involves wound irrigation and decontamination of the wound.[32] P.J.'s wound should be evaluated for deep tissue injury, devascularization of any tissue, and bone injury. Loose suturing or closure with adhesive strips is appropriate for lacerations after irrigation.[32] Although the safety of closure of bite wounds has been debated, a good therapeutic response has been obtained after the closure of wounds.

CASE 74-7, QUESTION 2: Because P.J. has several punctures that are difficult to irrigate, he is a candidate for antibiotic therapy. Which antibiotic(s) should he receive?

The need for antibiotics is controversial and guided by wound severity and patient immunocompetency.[2,34] The patient should receive a course of antibiotics if the wound involves the hand or is near joints, if it involves deep punctures or is difficult to irrigate, if the patient is immunocompromised (e.g., diabetes, splenectomy), or if the wound is not well perfused.

Antibiotics are not required for dog bites in which no deep tissue injury is present and the wound can be well irrigated, particularly if the wound is on the lower extremities in healthy adults or children.[32]

The selection of the appropriate antibiotic is based on the most likely pathogens from the specific animal bite. Although P. multocida often is considered the primary pathogen of dog bites, antibiotic coverage also must address the other common pathogens. Monotherapy with amoxicillin/clavulanate 875/125 mg orally every 12 hours is recommended.[2,32] Alternative options include second-generation cephalosporins (e.g., cefuroxime) plus an agent with anaerobic coverage (clindamycin or metronidazole). If the patient is allergic to penicillin, doxycycline, moxifloxacin, or a carbapenem provides adequate coverage.[2] In all cases, patients should be instructed to watch for improvement; if the wound does not heal or it worsens within 48 hours, the patient needs to be re-evaluated. Antibiotic treatment should not extend beyond 5 days unless signs of an infection remain. If the patient presents with an established infection, parenteral therapy is warranted if the infection is over a joint, has lymphatic spread, or involves the hand or head. Parenteral therapy should be continued until the infection has resolved, and therapy should then be continued with oral antibiotics for at least 7 days or until all clinical signs of the infection have resolved.

Prophylaxis for rabies is required only if the animal is from an area with endemic rabies or if the bite was the result of an unprovoked attack by a wild animal.[32] The local health board should be contacted to determine the recent rabies risk in the area. If P.J. has not received a tetanus toxoid booster within the past 5 years, a booster should be administered. If P.J. has never been immunized for tetanus, tetanus immune globulin should be administered in addition to the tetanus toxoid.

HUMAN BITE WOUNDS

CASE 74-8

QUESTION 1: C.K., a 40-year-old man, presents with a sore arm 24 hours after receiving a bite to his left forearm by his neighbor in a “discussion over property boundaries.” C.K. was previously healthy and has no chronic diseases. A 6 × 8 cm area of his left forearm is swollen and erythematous, and includes several distinct puncture marks consistent with a human bite. No joint deformity or bone abnormality is detected on clinical examination. How should C.K. be treated?

Treating a human bite is similar to any other laceration, including cleansing, irrigating, exploring, debriding, draining, excising, and suturing, as required.[32] All human bites should be cleansed as soon as possible, and any lacerations or punctures irrigated copiously. Surgical exploration with debridement, drainage, or excision should be undertaken if deeper tissues may have been injured or if pus collection could have occurred. With evidence of pus accumulation in his wound, the area should be explored and drained. E.D. also should receive systemic antibiotic therapy to eradicate potential infecting organisms. If the wound is severe (i.e., involves subcutaneous tissues, a joint, or a large area) or if the patient is unlikely to be compliant with oral antibiotics, parenteral administration of antibiotics is required. The most common pathogens in human bites are β-hemolytic streptococci, S. aureus, Eikenella corrodens, Fusobacterium, Peptostreptococcus, Prevotella, and Porphyromonas sp. Corynebacterium subspecies.[2] Treatment with amoxicillin/clavulanate, ampicillin/sulbactam, or ertapenem is appropriate. For penicillin-allergic patients, alternatives include ciprofloxacin or levofloxacin plus metronidazole or moxifloxacin alone.

Prevention and Treatment of Infections in Neutropenic Cancer Patients

Richard H. Drew

CORE PRINCIPLES	CHAPTER CASES
DEFINITIONS	
① As a consequence of select cancer chemotherapies, patients may experience neutropenia (defined as an absolute neutrophil count <500 cells/µL or anticipated to drop to <500 cells/µL within 48 hours) and fever (defined as a single oral temperature of ≥38.3°C [101°F] or a temperature of ≥38.0°C [100.4°F] for >1 hour).	**Case 75-1 (Question 4)**
② Bacteria are the primary pathogens associated with infection in febrile neutropenic patients (especially those occurring early).	**Case 75-1 (Questions 1, 6)**
CLINICAL PRESENTATION	
① Fever is usually the earliest (and often the only) sign of infection.	**Case 75-1 (Question 4)**
② An accurate history and complete physical examination should be completed. Chest radiographs and oximetry should be completed if signs and symptoms point to the respiratory tract.	**Case 75-1 (Question 5)**
③ Before antibiotics are initiated, two sets of blood cultures (with each set consisting of two culture bottles) should be obtained. Additional site-specific cultures should also be obtained if such infections are suspected. A complete blood count, serum electrolytes, coagulation, C-reactive protein, urinalysis, and assessment of organ function (e.g., liver and kidney function) should be assessed.	**Case 75-1 (Question 5)**
KEY TREATMENT INFORMATION	
① Risk stratification should be undertaken to identify patients most likely to experience significant infection-related complications. Patients at highest risk include those with prolonged (>7 days) and profound (<100 cells/µL) neutropenia or select comorbidities (hypotension, severe mucositis interfering with swallowing or causing diarrhea, pneumonia, new-onset abdominal pain, hepatic or renal insufficiency, or neurologic changes). Highest-risk patients should be considered for antibacterial and antifungal prophylaxis.	**Case 75-1 (Questions 2, 3, 7)**
② In the absence of evidence of site- or pathogen-specific etiologies or clinical instability, initial empiric monotherapy is most commonly an	**Case 75-1 (Questions 7–9),** **Case 75-2 (Questions 1, 2, 4,**

antipseudomonal third-generation cephalosporin (e.g., ceftazidime), a fourth-generation cephalosporin (e.g., cefepime), or an antipseudomonal carbapenem (e.g., imipenem–cilastatin or meropenem). Prolonged infusion of β-lactam (3-4 hours) should be considered in order to optimize their pharmacodynamic properties. Additional agents may be added (such as vancomycin, an aminoglycoside, or fluoroquinolone) to initial therapy in patients who are hemodynamically unstable. Antiviral therapy is generally restricted to patients with serologic or clinical evidence of viral infection.	**5),** **Case 75-4 (Question 4)**

MONITORING PARAMETERS

① The need for (and timing of) modification of the initial empiric therapy is dependent on the risk group (i.e., low vs. high risk), establishment of an infection site or causative pathogen, persistence or defervescence of fever, and clinical stability.	**Case 75-2 (Question 6)**

② High-risk patients unresponsive to initial empiric antibacterial therapy should be considered for the addition of antifungal therapy at days 4 through 7. In addition to coverage for Candida species, highest-risk patients with persistent or recurrent fever after 4 to 7 days of appropriate antibacterial therapy with prolonged (i.e., >10 days) neutropenia should be considered for antimold therapy. Low-risk patients who are clinically stable do not routinely need antifungal therapy.	**Case 75-3 (Questions 1, 2),** **Case 75-4 (Questions 1, 2)**

THERAPEUTIC CONTROVERSIES

① The role of vancomycin as part of the initial empiric regimen remains controversial. In general, routine use of vancomycin as part of initial empiric therapy for fever in neutropenic patients without other evidence of infection should be discouraged (except in clinically unstable patients).	**Case 75-2 (Question 3)**
② The ideal initial empiric antifungal agent is debatable. However, patients receiving fluconazole prophylaxis requiring addition of empiric antifungals should be considered for antifungals with activity against azole-resistant Candida species and mold infections.	**Case 75-4 (Questions 3, 4)**
③ Although hematopoietic colony-stimulating factors prevent neutropenia in high-risk cancer patients, use of these agents as treatment of febrile neutropenia unresponsive to antibiotics remains controversial.	**Case 75-1 (Question 3),** **Case 75-4 (Question 5)**

Many patients with both solid tumor and hematologic malignancies have had their lives prolonged through therapeutic advances in chemotherapy, immunotherapy, and hematologic stem cell transplantation (HSCT). Despite such advances, infectious complications continue to be a major cause of morbidity and mortality in these patients. Risk assessment, prevention, rapid detection, and effective management of infections, while a major challenge, can lead to improved outcomes in such immunocompromised hosts.[1],[2]

This chapter focuses on infectious complications in patients with immunosuppression as a consequence of cancer. The following topics are addressed: risks and epidemiology of infection, principles of prophylactic antimicrobials, empiric initial antibacterial selection, modification and duration of therapy, empiric antifungal and antiviral use, and the use of hematopoietic growth factors.

RISK FACTORS FOR INFECTION

Patients are rendered immunocompromised when there is a significant disruption or deficiency of one or more of the host defenses as a result of the underlying disease or chemotherapy. These risk factors include neutropenia and impairment in both humoral (antibody and complement) and cell-mediated immune defenses. Disruption of barriers to infection resulting from chemotherapy-related damage to skin and mucosal barriers further increases the risk of infection. As a result, bacteria, fungi, viruses, and (less commonly) protozoa may infect various sites (depending on the specific immunodeficiency).

Neutropenia

Granulocytes, or granular leukocytes, represent an important defense against bacterial and fungal infections. Neutropenia (a reduction in the number of circulating granulocytes or neutrophils) predisposes the host to infections. The terms granulocytopenia and neutropenia are often used interchangeably. The degree of neutropenia is expressed in terms of the absolute neutrophil count (ANC) or the total number of granulocytes (polymorphonuclear leukocytes and band forms) present in the circulating pool of white blood cells (WBCs).

For purposes of guideline development and clinical trials, neutropenia is most commonly defined as an ANC less than 500 cells/µL or less than 1,000 cells/µL with an anticipated to drop to less than 500 cells/µL within 48 hours.[2–4] The risk, severity, and type of infection in the neutropenic patient are proportional to the severity, rate of decline, and duration of neutropenia.[5] In general, the relative risk of infection is low when the ANC exceeds 1,000 cells/µL, with the frequency and severity of infection inversely proportional to the ANC.[3],[5,6] Because the ANC drops to less than 500 cells/µL, the risk of infection rapidly increases. Conversely, recovery of the ANC is one of the most important factors determining the outcome of infectious complications in the neutropenic patient. Febrile patients with short durations of neutropenia (≤7 days) or in whom neutropenia is not severe (<100 cells/µL) less frequently experience serious, life-threatening infections.[2,3,7] In contrast, patients with severe neutropenia lasting more than 7 days are at significant risk of severe infection.[2,3,8]

Damage to Physical Barriers

The intact skin and mucosal surfaces of the body (GI, sinus, pulmonary, and genitourinary) constitute the host's primary physical defense against microbial invasion. The integrity of this physical barrier may be disrupted by tumor, treatment (e.g., surgery, radiation), or various medical procedures (e.g., insertion of intravenous [IV] or urinary catheters, venipuncture, measurement of rectal temperature). Device-related infections, including those associated with central venous catheters, are commonly caused by migration of skin flora (e.g., staphylococci) through the cutaneous insertion site. Infections secondary to damaged mucosal lining of the gastrointestinal (GI) tract such as mucositis (usually secondary to chemotherapy or graft-versus-host disease [GVHD]) are usually caused by enteric bacteria and fungi such as Candida species.

Malignancy-Related Alterations in the Immune System

Malignancies such as leukemia [acute and chronic], lymphoma (e.g., non-Hodgkin lymphoma) and myelodysplastic syndrome may invade bone marrow, resulting in leukopenia. This is most notable in patients with advanced or refractory malignancy, which may reflect either bone marrow invasion or as a consequence of multiple courses of immunosuppressive chemotherapy. In contrast, predisposition to infection in patients with solid tumors is often associated with anatomic abnormalities (such

---

as obstruction or erosion). Such risks may be enhanced as a consequence of surgery, chemotherapy, and/or radiation to correct the underlying tumor.

Patients with immunoglobulin deficiencies (e.g., hypogammaglobulinemia, chronic lymphocytic leukemia, or splenectomy) are at increased risk for infections with encapsulated bacteria, which undergo antibody opsonization for efficient phagocytosis. Such bacteria include Neisseria meningitidis, Haemophilus influenzae, and Streptococcus pneumoniae. Hodgkin disease, organ transplantation, and human immunodeficiency virus (HIV) disease can disrupt the cellular immune system, increasing the risk for infections with obligate and facultative intracellular organisms such as mycobacteria, Listeria, Toxoplasma, viruses, and fungi. Certain hematologic malignancies and myelodysplastic syndromes may also be associated with immunodeficiencies secondary to replacement of leukocytes with malignant cells.

Medications Impacting Host Defenses

Some chemotherapeutic agents (such as fludarabine) have profound effects on both cellular and humoral defenses.[9],[10] Corticosteroids exert their immunosuppressive effects on the cellular immune system, particularly at the T lymphocyte and macrophage level. Therefore, patients receiving corticosteroids (such as HSCT recipients with GVHD) have increased susceptibility to viral, bacterial, protozoal, and fungal infections.[11] Infectious complications secondary to glucocorticoids are dose-dependent. The risk of infection increases with daily doses greater than 10 mg or cumulative doses greater than 700 mg of prednisone or its equivalent.[11] Thus, patients receiving corticosteroids in either high doses (>20 mg prednisone or its equivalent daily) or for prolonged periods are at increased risk for infections caused by opportunistic pathogens. In addition, corticosteroids may blunt the usual signs of infection such as fever and inflammation. Severe cell-mediated immunodeficiency may also be caused by GVHD and its treatment.[2],[3,9] More recently, chemotherapeutic monoclonal options (such as alemtuzumab, bortezomib, rituximab, and ofatumumab) significantly weaken the immune system, predisposing recipients to viral, bacterial, and fungal infections.[12],[13]

Colonization or Prior Infection

Colonization is characterized as isolation of an organism from any particular site (e.g., stool, nasopharynx) without clinical signs of infection. Most infections in neutropenic patients are caused by either the host's endogenous microflora or hospital-acquired pathogens that have colonized the alimentary tract, upper respiratory tract, or skin. Therefore, microbial colonization can be a prerequisite to infection in neutropenic patients. This is perhaps best studied in patients colonized with methicillin-resistant Staphylococcus aureus (MRSA). Prior infection (especially in the pre-engraftment phase of HSCT recipients) is a risk factor for infection during immunosuppression, particularly for viral infections (such as cytomegalovirus [CMV], herpes simplex virus [HSV], and Varicella zoster virus [VZV]). Infections with these pathogens during immunosuppression are generally considered to be a consequence of latent infection rather than new infection.[2],[3,9,14,15]

Hematopoietic Stem Cell Transplantation

Transplantation of bone marrow predisposes patients to the development of opportunistic infections secondary to both intensive immunosuppressive therapy and transmission.[9] These infections may be acquired or may represent reactivation of latent host infection. The introduction of new therapeutic approaches for treatment of the underlying malignancy (including nucleoside analogs and monoclonal antibodies to CD20 and CD52), along with use of unrelated stem cell donors, has increased the potential for infections in these patients.[9] When compared with autologous or syngeneic HSCT recipients, allogeneic HSCT patients have an increased risk of infection, particularly in those patients undergoing therapy for GVHD.[9] The pathogens causing infections vary with the time since transplantation. The use of immunosuppressives after transplantation (such as corticosteroids, antithymocyte globulin, and alemtuzumab) also significantly increases the risk for infection.[9]

Radiation Therapy

Side effects associated with the use of radiation therapy for the treatment of malignancy (e.g., mucositis, skin breakdown, or reduction in blood counts) also predispose a patient with neutropenia to infection.

Functional Asplenia

The spleen is responsible for production of opsonizing antibodies, assisting in protection against encapsulated bacteria (such as S. pneumoniae, H. influenzae, and N. meningitidis). Functional asplenia may occur secondary to irradiation or as a complication of GVHD.[3]

MOST COMMON PATHOGENS

CASE 75-1

QUESTION 1: B.C., a 41-year-old woman, was admitted to the cancer center for placement of a central IV catheter for administration of chemotherapy to treat acute nonlymphocytic leukemia in relapse. She was diagnosed 2 years ago and was treated with cytarabine plus daunorubicin, which resulted in a complete remission for 33 months. On this admission, she will be treated with high-dose cytarabine plus mitoxantrone for reinduction. What are the most likely pathogens to cause infection in patients like B.C. during periods of chemotherapy-induced neutropenia?

Bacteria are the primary pathogens associated with infection in febrile neutropenic patients, especially those occurring early.[16] Bacteremia (reported in approximately 25% of febrile neutropenic patients) is most often caused by aerobic gram-negative bacilli (including Pseudomonas aeruginosa, Escherichia coli, and Klebsiella pneumoniae) or aerobic gram-positive cocci (i.e., coagulase-negative staphylococci, S. aureus, enterococci, viridans streptococci).[17] Since the mid-1990s, the proportion of gram-negative infections has decreased with a proportional increase in gram-positive infections.[2],[18] Gram-positive bacteria now account for approximately 60% to 70% of microbiologically documented infections in neutropenic cancer patients.[2],[19] This is likely attributable (in part) to the frequent use of indwelling IV catheters, intensive chemotherapy, and widespread use of broad-spectrum antibiotics.

S. aureus (including MRSA) and coagulase-negative staphylococci, streptococci (including S. pneumoniae and viridans streptococci), and Corynebacterium species are increasingly important pathogens.[19] Moreover, enterococcal infections (including vancomycin-resistant enterococci [VRE]) are increasing in frequency. Meningitis caused by the intracellular organism Listeria monocytogenes can be observed in patients with defective cellular immunity caused by disease or prolonged corticosteroid use. In general, anaerobic bacteria are an

---

infrequent cause of infection in granulocytopenic patients with hematologic malignancies.[20] However, they should be suspected in patients with GI malignancies or with significant disruption of the GI tract.[20] Clostridium difficile is another anaerobic pathogen that may cause infection in this population.

Pneumocystis jiroveci (formerly known as Pneumocystis carinii or PCP) is a pathogen responsible for lung infections primarily in patients with HIV infection. However, PCP can also be responsible for lung infections in some cancer patients.[21],[22] Seen predominantly in patients with solid tumors or hematologic malignancies receiving long-term corticosteroids, PCP may present as subacute, febrile, hypoxemic, and diffuse pulmonary involvement.[21],[22]

Invasive fungal infections (IFIs) are a major cause of morbidity and mortality among neutropenic cancer patients and patients undergoing HSCT.[23],[24] The incidence of invasive fungal infections in febrile neutropenic patients varies widely because of differences in definitions, methods of detection, patient populations, and prior use of antifungal prophylaxis. In general, patients with hematologic malignancies have a higher incidence of fungal infections than those with solid tumors.[25] Similar to the risk of bacterial infections, the risk of invasive fungal infections is also related to the degree and duration of neutropenia. IFIs tend to occur later in the illness. Patients with prolonged neutropenia (>7 days) or with acute myelogenous leukemia (AML) undergoing intensive induction therapy, allogeneic HSCT recipients, and those undergoing therapy for GVHD are at increased risk of acquiring systemic fungal infections.[23],[24] Up to 50% of patients who die during prolonged periods of neutropenia have evidence of deep-seated mycoses.[23] Before the use of fluconazole prophylaxis in selected populations, Candida species were responsible for most invasive fungal infections. Most fungal infections in neutropenic cancer patients are caused by Candida and Aspergillus species.[26–28] Other less common but important pathogenic fungi are those associated with zygomycosis (e.g., Mucor and Rhizopus species) and other emerging pathogens (non-albicans Candida, Trichosporon beigelii, Malassezia species, Cryptococcus neoformans, and Fusarium species).[26–28] Today, invasive infections attributable to Aspergillus species and other molds are a major cause of IFI-related death (particularly in those with prolonged neutropenia and GVHD).[23],[29] Recent reports of improved survival from IFIs are likely related to newer prophylactic and treatment options and advances in cancer chemotherapy.[30]

As previously stated, most viral infections in neutropenic cancer patients are caused by a reactivation of latent infection rather than new infection.[2],[3,9,14,15] These may include hepatitis B virus (HBV), herpes simplex virus (HSV), and Varicella zoster virus (VZV). Other viruses, such as CMV, can be either reactivation or newly acquired during HSCT. The risk of viral reactivation in these patients increases in patients who are seropositive prior to transplant. Respiratory viruses (e.g., respiratory syncytial virus [RSV], influenza, parainfluenza), GI viruses (such as rotavirus and norovirus), and other seasonal viruses may occasionally cause infection in this population.

STRATIFICATION FOR RISK OF INFECTION

Risk stratification to identify patients most likely to experience neutropenia has important implications for decisions about prevention, diagnostic strategies, empiric therapy (selection, route of administration, duration), and site of care.[2–4,9,14,15,31] In general, the underlying malignancy, status of disease (i.e., active vs. inactive), degree and duration of neutropenia, and chemotherapy type impact risk. Patients at highest risk of complications include those with prolonged (>7 days) and profound (<100 cells/μL) neutropenia or with select comorbidities (hypotension, severe mucositis interfering with swallowing or causing diarrhea, pneumonia, new-onset abdominal pain, hepatic or renal insufficiency, or neurologic changes).[3],[4] In contrast, patients with shorter (≤7 days) anticipated durations of neutropenia without significant comorbidities are generally considered at low risk of complications of infection.[3],[4,32] Patients without fever but exhibiting new signs of infection should also be treated as high risk. Presenting signs and symptoms, cancer type, chemotherapy regimen, medical comorbidities, and prior history of febrile neutropenia (especially if severe or prolonged) should also be considered. Patients with select solid tumors (breast, lung, colorectal, ovarian) and lymphoma most frequently experience neutropenic fever. Chemotherapeutic regimens associated with the highest (>20%) incidence of neutropenia are summarized in detail elsewhere[31] (see Section 17, Neoplastic Disorders).

The factors impacting risk have been utilized by the National Comprehensive Cancer Network in assigning infection risk in cancer patients as low, medium, and high.[3] Other risk assessment tools have been proposed,[3],[14,15] including the

Multinational Association for Supportive Care in Cancer (MASCC) index.[33] Age of at least 60 years, presence of hematologic malignancies with a history of prior fungal infections, severe symptoms (particularly hypotension), inpatient site of care, organ dysfunction (hepatic and renal), and presence of chronic obstructive pulmonary disease are important variables that result in a low MASCC score (i.e., <21), and (consequently) patients with any of these factors are considered at highest risk. Young patients (<20 years) with solid tumors and no or mild symptoms (including the absence of hypotension) or organ dysfunction are generally at low risk for complications.

PROPHYLAXIS AGAINST INFECTION

Infection Control

CASE 75-1, QUESTION 2: Should B.C. receive antimicrobial prophylaxis during the neutropenic period? If yes, which agents should be used?

Exogenous contamination can be prevented by strict protective isolation of patients in specially designed rooms that maintain a sterile environment. These laminar airflow rooms are ventilated with air that is passed through a high-efficiency particulate air filter, which removes greater than 99% of all particles larger than 3 μm. Total protective isolation is accomplished by strict isolation in conjunction with the administration of sterile food and water, local skin care, and intensive microbial surveillance. However, this regimen is burdensome, difficult to accomplish, and expensive, and is recommended only for high-risk patients (such as allogeneic HSCT recipients).[4] HSCT recipients and candidates undergoing conditioning therapy should avoid exposure to plants, flowers, and certain foods (such as uncooked fruits and vegetables), which increase the risk of exposure to fungi.[9],[34] Close attention and adherence to adequate hand-washing procedures is essential. In addition, contact isolation is advocated in circumstances in which the patient may be colonized or infected with resistant organisms (such as MRSA, VRE, or multidrug-resistant gram-negative pathogens). Finally, isolating the patients from family or caregivers with potentially contagious respiratory viral illnesses is advocated.

Antimicrobial Prophylaxis

Early administration of antibiotics (i.e., antibacterials, antifungals, and antivirals) during the afebrile, neutropenic period in select high-risk patients may result in a reduction in the number of febrile episodes and subsequent risk of infection. The goals of such prophylactic regimens are intended to reduce pathogenic endogenous microflora or prevent the acquisition of new microorganisms. The potential benefits of such prophylaxis must outweigh the risks of antibiotic-related adverse effects including drug interactions, the development of resistance (most notable with antibacterials), and the potential for superinfection. Use of agents for prophylaxis (such as a fluoroquinolone for antibacterial prophylaxis) may also preclude the use of the class as empiric therapy for subsequent suspected or documented infections.

In general, lowest-risk cancer patients (such as those receiving standard chemotherapy for many solid tumors, and neutropenia anticipated to be <7 days) should not routinely receive antibacterial and antifungal prophylaxis.[3],[4] Prophylactic administration of antivirals in such patients is generally restricted to those with a history of prior infection (such as HSV). In contrast, allogeneic HSCT recipients and those with acute leukemia, receipt of alemtuzumab therapy, GVHD requiring high-dose steroids, and prolonged (>10 days) neutropenia are at highest risk of infection and should receive antibacterial, antifungal, and (in select cases) antiviral prophylaxis.[3],[4]

ANTIFUNGALS

CASE 75-1, QUESTION 3: Should antifungal prophylaxis be used in B.C.? What is the role of hematopoietic growth factors?

Routine antifungal prophylaxis is not indicated in patients with neutropenia at low risk of infection. However, select patients are at increased risk of developing systemic fungal infections.[23] Because of the frequency with which such infections are encountered, difficulties in establishing a diagnosis, poor response rates in patients with serious invasive infection who are immunocompromised, and effective prophylactic strategies are necessary in select intermediate and all high-risk patients. In patients for whom antifungal prophylaxis is indicated, the choice of the agent depends largely on the risk of invasive mold infections.

ANTIFUNGAL AGENTS

Nonabsorbable Antifungal Agents

Nonabsorbable antifungal agents, such as oral nystatin,[35],[36] clotrimazole,[37] and oral amphotericin B,[38] have been studied. Although oral amphotericin B and clotrimazole reduce the frequency of oropharyngeal candidiasis, none of these antifungals has a role as primary prophylaxis of invasive fungal infections.[9] In attempts to enhance activity while minimizing side effects associated with IV administration, aerosolized delivery of amphotericin B deoxycholate has been investigated for the prevention of invasive fungal infections in this patient population,[39] and aerosolized liposomal amphotericin B has been used in leukemic and HSCT patients.[40] Although promising, the optimal dose, delivery device, and duration for aerosol administration of amphotericin B preparations have not yet been determined.

Amphotericin B

The use of systemic antifungals for prophylaxis has been summarized elsewhere.[41] Many of the earlier studies evaluated the prophylactic role of IV amphotericin B.[42–44] In general, use of amphotericin B deoxycholate is limited in this setting due to its toxicities (i.e., infusion-related reactions, nephrotoxicity, and electrolyte disturbances) relative to available options for prophylaxis. Consequently, amphotericin B is generally discouraged for primary prophylaxis in high-risk patients, unless the patient is unable to receive other mold-active prophylactic agents. If required, a lipid-based formulation would be preferred, especially in patients at increased risk of amphotericin B-induced nephrotoxicity.

Systemic Azole Antifungals

Systemic azole antifungals (e.g., itraconazole, fluconazole, voriconazole, posaconazole) may also be considered in select patients, but differ considerably in their spectrum of activity, adverse reaction profile, drug interactions, and need for serum concentration monitoring. The newest member of this class, isavuconazole, while representing potential advantages over comparator agents, has not yet been studied in such a setting.

Itraconazole has been well studied as an antifungal prophylaxis. In addition to in vitro activity against many Candida species (e.g., Candida albicans), itraconazole is active in vitro against Aspergillus species and reduces systemic Candida infections.[45–47] Although itraconazole oral solution demonstrates improved bioavailability over the capsule formulation, it is associated with significant GI intolerance.[48],[49] Itraconazole is contraindicated in patients with reduced cardiac ejection fraction due to its negative inotropic effect. Use of newer azoles (such as posaconazole and voriconazole) has largely replaced the use of itraconazole for prophylaxis in patients at increased risk of mold infections (such as those patients undergoing immunosuppressive therapy for GVHD).

Fluconazole prophylaxis decreases the frequency of both superficial (e.g., oropharyngeal candidiasis) and systemic fungal infections in HSCT patients[50],[51] but not in patients with leukemia.[7],[52,53] Fluconazole is available as both oral and IV formulations, and its oral bioavailability is not significantly influenced by changes in gastric acidity. The IV formulation enables fluconazole to be administered to critically ill patients or patients who have difficulty swallowing. Although fluconazole is useful prophylactically, concern about its lack of reliable in vitro activity against molds limits its use in highest-risk patients. An increased frequency of isolation of non-albicans Candida (e.g., Candida krusei, Candida glabrata, Candida parapsilosis) has also been noted in some institutions.[54]

Posaconazole has demonstrated improved survival, a reduction in proven or probable IFI, and a reduction in invasive aspergillosis when compared with standard prophylaxis (either itraconazole or fluconazole) for the prevention of fungal infection in patients undergoing chemotherapy for AML or myelodysplastic syndrome.[55] Posaconazole was also effective prophylaxis in allogeneic HSCT recipients undergoing therapy for GVHD.[56] Posaconazole is currently available in both oral (solution and tablet) and parenteral (IV) formulations. The oral solution has been replaced largely by the tablet formulation due to its improved bioavailability and reduced dependency on the need for coadministration with high-fat meals for optimal absorption.[57],[58] Absorption of oral posaconazole may be reduced in patients with mucositis and in patients receiving acid-suppressing therapy.[59] In addition, the use of IV posaconazole is not recommended in patients with significant renal impairment because of the potential toxicity of the vehicle.

Voriconazole's use as an antifungal prophylaxis in cancer patients at increased risk of mold infections is not well supported by clinical data despite its established use in the treatment of invasive aspergillosis.[60–62] Side effects (most notably hepatotoxicity, rash, phototoxicity) and the increased potential (relative to other azoles and the echinocandins) for drug interactions with voriconazole may limit its prophylactic use to patients at highest risk of mold infections. Similar to IV posaconazole, the use of IV voriconazole should be avoided in patients with significant renal impairment because of the potential toxicity of the vehicle. Oral voriconazole should be administered either 1 hour before or after a meal to optimize its absorption.

Echinocandins

The echinocandins (e.g., caspofungin, micafungin, and anidulafungin) may be useful as a prophylactic strategy in high-risk patients. Micafungin has been compared with fluconazole in autologous and allogeneic HSCT recipients.[63] Based on a composite endpoint (which included absence of breakthrough fungal infection and absence of empiric modifications to the antifungal regimen owing to neutropenic fever), micafungin was found to be superior. Although breakthrough candidemia, survival, and adverse events were similar in both groups, a trend toward a reduction in invasive aspergillosis in the allogeneic HSCT population was noted in the micafungin group. Micafungin is currently US Food and Drug Administration (FDA)–approved for the prevention of Candida infections in HSCT patients.

SELECTION AND MONITORING OF PROPHYLACTIC ANTIFUNGALS

The use of primary antifungal prophylaxis in cancer patients with neutropenia should be reserved for patients at intermediate or high risk of invasive fungal infections (IFIs).[3],[4] Patients with acute lymphocytic leukemia receiving remission or salvage induction chemotherapy are at intermediate risk and should be considered for prophylaxis. Although autologous HSCT recipients may not routinely benefit from fungal prophylaxis (most notably those without evidence of mucositis), those with prolonged neutropenia, mucosal damage, or receipt of purine analogs should receive primary prophylaxis.[9] Acceptable options for prophylaxis against Candida species include azoles (e.g., fluconazole, itraconazole, voriconazole, posaconazole) and the echinocandins (micafungin and caspofungin).[3],[4] Of these options, fluconazole is the most commonly used agent. In the setting of colonization with fluconazole-resistant Candida species (such as C. krusei, C. glabrata), an echinocandin (such as micafungin) is preferred.[3],[4,9,63] In contrast, patients with higher risk for mold infections (such as AML/MDS patients, or those with GVHD receiving intensive immunosuppressive therapy regardless of neutropenia) should be considered for prophylaxis with mold-active drugs (such as posaconazole, voriconazole, echinocandins, or amphotericin B) during periods of risk.[3],[4,9] Mold-active agents are also recommended in the setting of anticipated periods of prolonged (at least 2 weeks) neutropenia, or prolonged neutropenia immediately before HSCT.[4]

Use of itraconazole, posaconazole, and voriconazole for prevention of fungal infections should be avoided in patients receiving vinca alkaloids (such as vincristine) due to their inhibition of the cytochrome P4503A4 (CYP3A4) isoenzyme and the resulting reduction in drug clearance of the vinca alkaloid. Fluconazole, while a CYP34A inhibitor, is less potent than these other azoles. Voriconazole also inhibits other cytochrome P450 isoenzymes to the greatest extent, expanding its potential for significant drug–drug interactions. The impact of isavuconazole on vinca alkaloids has not yet been report, but the potential for interactions does exist.

Prophylaxis is generally continued during the period of neutropenia. In those with acute leukemia, myelodysplastic syndrome (MDS), or autologous HSCT recipients, prophylaxis should continue until day 75 after transplant or through induction therapy for patients with leukemia.[64] Patients with a history of documented Aspergillus infection undergoing intensive chemotherapy should be considered for voriconazole.[9] Although the addition of a second prophylaxis (e.g., echinocandin) may be considered, the benefits of combination therapy for secondary prophylaxis are unknown.

Prophylactic use of antifungals may also be used in patients with a prior history of invasive disease due to Candida spp. or filamentous fungi. Such prevention (known as secondary prophylaxis) should be considered in such patients during subsequent chemotherapy or stem cell transplantation for the duration of immunosuppression.

In contrast to the predictable serum concentrations resulting from fluconazole administration, itraconazole, voriconazole, and posaconazole exhibit significant variability in drug concentration, most notably following oral administration. Therefore, serum concentration monitoring of these agents may help assure optimal drug exposure while reducing the potential for concentration-related toxicities. However, determination of definitive target concentrations for prophylactic use is hampered by the lack of controlled, prospective clinical trials. For itraconazole, steady-state trough concentrations of >0.5 mcg/mL or greater have been recommended. Voriconazole steady-state serum concentration of >0.5 to 4 mcg/mL has been recommended for use as prophylaxis. Studies regarding the optimal trough concentration of posaconazole for prophylaxis differ, but range between 0.5 and 0.7 mcg/mL.[65],[66]

NONABSORBABLE ANTIBACTERIALS

Because the GI tract is an important reservoir of potential pathogens, gut decontamination has been investigated.[19] However, use of nonabsorbable antibacterial agents has been replaced by oral, absorbable antibiotics.[3],[4]

ABSORBABLE (SYSTEMIC) ANTIBACTERIALS

Trimethoprim–Sulfamethoxazole

Although trimethoprim–sulfamethoxazole (TMP–SMX) decreases bacterial infections in neutropenic patients,[67],[68] it may not reduce mortality in this patient population. The potential benefits of TMP–SMX prophylaxis must be carefully balanced against the potential for drug-induced bone marrow suppression, hypersensitivity reactions, hyperkalemia, nephrotoxicity, pancreatitis, the emergence of resistant organisms (e.g., E. coli), and the development of superinfections. In addition, leukemic patients receiving mucotoxic chemotherapy and TMP–SMX prophylaxis may be at increased risk for infections caused by viridans streptococci.[69],[70] Therefore, TMP–SMX should not be routinely used for primary prophylaxis (except as noted below).

TMP–SMX prevents P. jiroveci (PCP) pneumonia in both ALL and HSCT patient populations. Patients with malignancy at highest risk for experiencing P. jiroveci (PCP) pneumonia (i.e., patients with acute lymphocytic leukemia receiving intensive chemotherapy, those with acquired immunodeficiency syndrome, allogeneic HSCT recipients, those receiving alemtuzumab, patients with GVHD, and those in whom neutropenia is anticipated to exceed 10 days) should receive TMP–SMX prophylaxis.[3],[9] Recipients of T-cell-depleting agents (e.g., fludarabine or cladribine), cancer patients receiving prolonged or high-dose corticosteroids (>20 mg of prednisone or its equivalent daily), and autologous HSCT recipients should also be considered for prophylaxis with TMP–SMX.[9] In such settings, primary prevention should be continued for up to 6 months (in the case of HSCT recipients) or longer (in cases in which immunosuppression is continued). In the setting of alemtuzumab therapy, such prophylaxis would generally continue for at least 2 months and until the CD4 count exceeded 200 cells/µL.[3] In patients requiring PCP prophylaxis but unable to tolerate TMP–SMX, patients should receive alternate prophylaxis with either atovaquone, dapsone, or pentamidine (either IV or via aerosol).[3],[9]

Fluoroquinolones

The fluoroquinolones ciprofloxacin and levofloxacin are used by some centers as prophylaxis for adult patients at high risk of infection.[71],[72] Of concern, however, is the increasing frequency of gram-positive infections (including viridans streptococci) and resistant gram-negative bacilli (most notable in P. aeruginosa and E. coli)[73] in patients receiving fluoroquinolone prophylaxis.[69],[70,74,75] Meta-analyses report reductions in mortality in high-risk patients receiving prophylaxis with these fluoroquinolones.[71],[76] Because

---

fluoroquinolone prophylaxis is offset by the emergence of resistant organisms, routine prophylactic use in low-risk patients should generally be avoided.[4] However, those at intermediate or high risk of bacterial infections (i.e., those patients with an ANC ≤100 neutrophils/μL for >7 days) should be considered for fluoroquinolone prophylaxis until either the onset of fever (at which time empiric antibacterials would be started) or resolution of severe neutropenia.[4],[9] Levofloxacin has been recommended over ciprofloxacin in patients at increased risk of oral mucositis-related infection with invasive viridans streptococci.[4] Regardless of the fluoroquinolone chosen, local resistance patterns should be closely monitored before such prophylaxis is chosen.

Penicillin

Because of the increased risk of invasive pneumococcal infections, select patient populations (notably asplenic patients, allogeneic HSCT recipients [owing to functional asplenia and impaired B-cell immunity], and those undergoing immunosuppression for GVHD) should be considered for prophylaxis with penicillin. In patients with chronic GVHD, penicillin prophylaxis may be continued during the administration of immunosuppressives. In HSCT recipients, prophylaxis should begin 3 months after transplant and continue for 1 year after transplant. Alternative prophylaxis should be considered in areas where penicillin resistance in pneumococci is significant.

ANTIVIRALS

Most HSV disease in cancer patients is a consequence of reactivation from latent infection. High-risk patients (e.g., seropositive for HSV undergoing allogeneic HSCT or induction or re-induction therapy for acute leukemia) or patients previously requiring treatment for HSV reactivation should be given antiviral prophylaxis. Both oral or IV acyclovir and oral valacyclovir are appropriate initial choices in most patients. Published data for famciclovir for this indication are lacking. Those receiving foscarnet or ganciclovir (most commonly for prevention and treatment of CMV infection) do not require additional prophylaxis for HSV, given the activity of these against H. simplex. Prophylaxis should be administered during periods of neutropenia and for at least 1 month after HSCT.[3],[4] The duration may be extended in those undergoing allogeneic HSCT with GVHD. Patients receiving alemtuzumab may also require extended prophylaxis of up to 2 months after completion of therapy or recovery of $CD4^+$ cells count >200 cells/µL, whichever is later.

Similar to HSV, VZV in cancer patients is most commonly reactivation. HSCT patients who are seropositive for VZV should also be given long-term prophylaxis (6–12 months for autologous HSCT and at least 1 year for allogeneic HSCT patients),[4] particularly with receipt of either bortezomib or alemtuzumab.[3] Extending prophylaxis in allogeneic HSCT patients should be considered in the setting of continued immunosuppressive therapy. Like for HSV, patients receiving alemtuzumab may also require extended prophylaxis of up to 2 months after completion of therapy or recovery of CD4+ cells count >200 cells/µl, whichever is later. Agents active against HSV are also useful for VZV prevention. In one study, low-dose (i.e., 500 mg/day, 3 times weekly) valacyclovir prophylaxis after a 35-day course of IV acyclovir is safe and effective in allogeneic HSCT recipients.[77]

Patients at highest risk of either CMV reactivation or primary infection (e.g., allogeneic HSCT patients, those receiving alemtuzumab, and those with GVHD requiring high-dose steroids) should be considered for antiviral prophylaxis against this pathogen. One strategy is the administration of all patients at risk (universal prophylaxis). Given the toxicity of ganciclovir IV, valganciclovir PO, foscarnet IV, and cidofovir IV (the most potent agents for CMV), a second strategy, known as preemptive, involves administration of antivirals prior to symptoms by following serologic evidence (based on CMV pp65 antigen or two consecutive CMV PCR tests) of viral replication. Foscarnet and cidofovir IV are generally reserved as second-line agents for preemptive therapy (such as in the setting of neutropenia secondary to ganciclovir). The potential role of valganciclovir PO (an oral pro-drug of ganciclovir) as a preemptive strategy in this population has been evaluated and is now considered a viable option in the absence of GVHD involving the GI tract.[78–82] Finally, a third prevention strategy is to combine use of less effective yet safer agents (such as acyclovir or valacyclovir) together with active surveillance (up to 6 months in allogeneic HSCT patients) and, when serologic evidence of virus replication exists, initiate PO valganciclovir or ganciclovir IV therapy. Surveillance for CMV may be extended in patients with chronic GVHD receiving immunosuppressive therapy until recovery of CD4+ count of 100 cells/µL or greater.

Patients with prior infections with hepatitis B virus (HBV) or hepatitis C virus (HCV) can experience reactivation of infection secondary to immunosuppressive therapy. Reactivation of infection can occur in patients infected with HBV undergoing immunosuppressive therapy (most notably in allogeneic HSCT recipients and those receiving anti-CD20 or anti-CD52 monoclonal antibodies). Therefore, serologic screening (utilizing testing for hepatitis B surface antigen [HBsAg] and hepatitis B core antibody [HBcAb]) is generally performed in patients at increased risk of infection. Prophylaxis should be considered in patients with positive tests.

Patients with one or more of these screening tests positive often undergo further testing for active viral replication (utilizing a quantitative PCR test for HBV DNA). Preemptive therapy should be considered in patient with evidence of viral replication. Despite limited data in cancer patients, the nucleos(t)ide analogs adefovir and tenofovir have largely replaced lamivudine monotherapy in such settings due to the high incidence of viral resistance with this strategy. Other agents considered for HBV prophylaxis may include entecavir and telbivudine.

Respiratory tract infections caused by RSV, influenza, and parainfluenza are less commonly observed in patients with neutropenia. Although response to influenza virus vaccine may be attenuated, patients undergoing cancer treatment should receive annual vaccinations with inactivated influenza vaccine.[4] Whenever possible, the timing of such vaccinations may be best between cycles (>7 days after or >2 weeks before next treatment). In contrast, immunocompromised patients should not receive the intranasal live virus vaccine.[4]

Hematopoietic Growth Factors

Hematopoietic colony-stimulating factors (CSFs) such as granulocyte CSF (G-CSF; filgrastim), pegylated G-CSF (pegfilgrastim), or granulocyte-macrophage CSF (GM-CSF; sargramostim) are important adjuncts in cancer patients.[83],[84] Studies in cancer patients receiving myelosuppressive or myeloablative chemotherapy have demonstrated that concurrent use of the CSFs can reduce the duration of neutropenia. The selection of one CSF agent over another is often based on practitioner preference rather than clinical data.

Hematopoietic growth factors (more specifically G-CSF [filgrastim] or pegylated G-CSF [pegfilgrastim]) reduce the risk of chemotherapy-induced febrile neutropenia.[10],[31,85–87] Risk factors for neutropenia include age (i.e., >65 years), medical history (including prior history of febrile neutropenic episodes, nutritional status, unstable comorbidities, and presence of active infections), disease characteristics (especially those involving bone marrow resulting in cytopenias), and myelotoxicity of the regimen (including both chemotherapy and radiation) used to treat the underlying malignancy.[31],[85–87] Routine use of CSFs for the prevention of febrile neutropenia should be discouraged in patients at low risk (<10%) of

febrile neutropenia.[4],[31,87] In contrast, guidelines advocate the use as primary prophylaxis in patients at high risk (>20%) of fever and neutropenia. Some guidelines also recommend administration of CSFs for primary prevention for patients >65 years with diffuse aggressive lymphoma treated with curative chemotherapy (especially in the setting of significant comorbidities and in those receiving select dose-dense chemotherapy regimens). Although benefits of CSFs are less clear in patients with intermediate risk (10%–20% risk of febrile neutropenia), they should be considered on a case-by-case basis.[84] CSFs are generally avoided as prophylaxis in patients undergoing radiation therapy concomitant with chemotherapy because of the potential for thrombocytopenia[88] or reductions in tumor response.[89] Administration is generally continued 3 to 4 days after chemotherapy administration and continued until a sufficient and stable postnadir ANC recovery is established.[10],[84] Pegylated G-CSF may be preferred in some settings owing to the convenience of single administration.[31],[90]

Consideration of the use of CSFs as secondary prophylaxis (i.e., prevention of febrile neutropenia in patients undergoing second or subsequent cycles of chemotherapy) should be based on repeated assessments of patient risk of febrile neutropenia.[84] Patients experiencing prior episodes of febrile neutropenia or neutropenia limiting the dose of chemotherapy without prior CSFs should be considered for secondary prophylaxis.[84]

Other Agents

Although beyond the scope of this chapter, select vaccinations have also been recommended for both autologous and allogeneic HSCT recipients (primarily caused by a decline in antibody titers to many vaccine-preventable diseases).[9] These include (but are not limited to) administration of pneumococcal, influenza virus and H. influenzae vaccines. Live vaccinations should be avoided in this population. However, because immune response may be altered immediately after transplant, delays of up to 3 months after cessation of immunosuppressive chemotherapy are recommended for many vaccines. In addition, serologic testing of antibody response is recommended in selected settings.[9]

Although data to support use are sparse, IV immunoglobulins have been recommended for HSCT recipients with severe hypogammaglobulinemia (i.e., serum immunoglobulin G level <400 mg/dL) and recurrent infections.[9] Intravenous immunoglobulins (IVIG) have been used as adjuncts in the prevention and treatment of CMV infections. In contrast, granulocyte transfusions have not been proven to be effective in either prevention or treatment of infection in the neutropenic cancer patient.[91]

INFECTIONS IN NEUTROPENIC CANCER PATIENTS

Clinical Signs and Symptoms

CASE 75-1, QUESTION 4: Seven days after completing chemotherapy, B.C. experienced a fever of 102°F (orally). Vital signs are blood pressure, 109/70 mm Hg; pulse, 102 beats/minute; and respirations, 25 breaths/minute. Physical examination demonstrates a clear oropharynx without exudates or plaques. Chest and cardiac examination are normal. The exit site for the Hickman catheter is clean and nontender without signs of erythema or induration. The perineum and rectum are nontender, and no masses are noted. Laboratory data are as follows:

Hematocrit, 20%
Hemoglobin, 7 g/dL
WBC count, 1,400 cells/μL, with 3% polymorphonuclear leukocytes (PMNs), 1% band forms, 70% lymphocytes, and 22% monocytes
Platelet count, 17,000 cells/L
Blood glucose, 160 mg/dL
Serum creatinine (SCr), 1.1 mg/dL
Blood urea nitrogen (BUN), 24 mg/dL
What are the signs and symptoms of infection in B.C.? What are the most common sites and sources of infection in patients such as B.C.?

B.C. has an ANC of 48 cells/μL (1,400 WBCs/μL × [0.03 PMNs + 0.01 bands]) and is therefore at high risk for infection.

Fever in neutropenic patients is defined as a single oral temperature of at least 38.3°C (101°F) or a temperature of at least 38.0°C (100.4°F) for more than 1 hour in the absence of an obvious cause.[3],[4] It is the earliest (and often the only) sign of infection in neutropenic patients, because typical signs can be modified or absent in this patient population.[4] However, only 48% to 60% of patients with febrile neutropenia have occult or documented infections.[3] Noninfectious sources of fever in the neutropenic cancer patient include inflammation, tumor progression, tumor lysis, adverse drug reactions, and transfusion reactions.[3],[14,15] Signs and symptoms consistent with a diagnosis of infection without fever should be considered to be infection in the neutropenic host until proven otherwise.[3]

In patients with documented infections, the most common sites are skin, mouth, throat, esophagus, sinuses, abdomen, rectum, liver, vascular access, lungs, and urinary tract.[3],[92] Although the lung is the most common site of serious infection in neutropenic cancer patients, fever and dry cough are often the only presenting signs of pneumonia.[92] The impaired inflammatory response results in scant sputum production, and sputum Gram stains often contain few PMNs. Radiologic evidence of a pulmonary infection can be minimal or absent, and the chest examination is frequently not diagnostic.[93] Pneumonia is associated with high mortality in neutropenic patients, particularly in the setting of bacteremia. In the presence of shock, a mortality rate of approximately 80% has been observed in these patients.[94]

Invasive procedures such as venipuncture, central IV catheter placement (e.g., Hickman catheter), and skin biopsies are associated with cellulitis and systemic infections. However, the typical signs and symptoms of infection (e.g., pain, heat, erythema, swelling) are often absent in part owing to inadequate granulocytes.[92] Colonization of these lesions may result in local infection and the potential for systemic dissemination of bacteria and fungi. Bacteremia occurs primarily from entry of bacteria through the skin or through unrecognized ulcerations in the GI and perirectal areas.

Confirmation of Infection

Because of the frequent lack of physical signs and symptoms of infection, the clinician must obtain an accurate history (including the cancer type and treatment regimen, new signs of infection, antimicrobial prophylaxis, prior infections, and comorbidities) and conduct a careful physical examination at the first sign of fever. A detailed search for subtle signs and symptoms of inflammation at the most common sites, such as the oropharynx, bone marrow aspiration sites, lung, periodontium, skin, vascular catheter access sites, nail beds, and perineum (including the anus) is necessary. Before antibiotics are initiated, two sets of blood cultures (with each set consisting of two culture bottles) should be obtained.[3],[4,14] In patients with indwelling central venous catheters, one of the two sets of blood cultures should be obtained from the catheter to help rule out catheter-related infection.[4] Diarrheal stools may be tested for the presence of C. difficile. Additional Gram stain and cultures (e.g., stool, urine, skin, IV site, respiratory specimens) should be obtained depending on signs and symptoms.[4] The yield from such cultures, however, may be affected by the prior or concurrent administration of prophylaxis.[2] Chest radiographs and oximetry should be obtained in the presence of respiratory symptoms.[4] Respiratory virus testing should take place for patients with upper respiratory tract infection symptoms (i.e., coryza) or cough.[4] In settings in which pulmonary aspergillosis is suspected, further radiologic evaluations (such as computed tomography scans) should be considered.[29] A complete blood count, serum electrolytes, coagulation, C-reactive protein, urinalysis, and assessment of organ function (e.g., liver and kidney function) should be obtained to assist in drug dosing and monitoring for treatment-related toxicities.[4]

Recent advances have been made in nonculture-based diagnostic tests that help support (or in some cases eliminate) the diagnosis of infection in these patients.[95] Such studies include C-reactive protein[96–98] and procalcitonin.[98–100] However, these tests are not routinely ordered, and their role in the treatment of the neutropenic cancer patient has not yet been established.[4] Galactomannan (specific for aspergillosis)[101] and β-D-glucan testing may assist in the diagnosis of fungal infections.[102],[103] Serial galactomannan testing has also been used preemptively to initiate antifungal therapy before overt signs and symptoms of invasive fungal infections occur.[104] In addition to other issues regarding sensitivity and specificity of these assays, both galactomannan and β-D-glucan are affected by prior or current receipt of antifungals.[29] At present, the use of these tests should be restricted to persistent fever despite other etiologic investigations.[4]

Significance of Colonization

CASE 75-1, QUESTION 5: How can an infection be confirmed in patients such as B.C.?

Several factors influence the colonization and subsequent infection by microorganisms in cancer patients. Organisms isolated from infected patients can be found in endogenous flora or acquired during hospitalization.[105] Factors leading to colonization include staff-to-staff and patient-to-patient transmission (e.g., lack of frequent and adequate hand hygiene), direct transmission from the environment (e.g., inadequately disinfected bathtubs, sinks, toilet bowls), foods (e.g., raw fruits and vegetables), inhalation from contaminated fomites (e.g., respirators, ventilating systems), and IV access devices. In addition to immunosuppression, the underlying malignancy and associated chemotherapy diminish the cancer patient's resistance to colonization and infection.

The acquisition of and subsequent colonization by potentially pathogenic microbes may be detected by serial surveillance cultures of specimens obtained from various body sites such as the nasopharynx, axilla, urine, and rectum. Such surveillance cultures may be useful for infection control purposes. However, little clinically useful information is gained in the absence of infection. Therefore, surveillance cultures are generally restricted to select patients for infection control purposes. In such cases, culture of the anterior nares (for MRSA) or rectal samples (for VRE or multidrug-resistant gram-negative bacilli) may be performed.

In summary, B.C.'s surveillance culture results indicate that she is colonized with several potential pathogens associated with infection in the immunocompromised host, but these results are probably not useful in selecting empiric antibiotics for her fever.

EMPIRIC ANTIBIOTIC THERAPY

Rationale

CASE 75-1, QUESTION 6: Routine surveillance cultures of swabs taken from B.C.'s axillae, nasopharynx, and rectum grew Corynebacterium jeikeium (axillae), S. aureus (axillae and nasopharynx), and Enterococcus faecium (rectum). What is the significance of these culture results? Should routine, serial surveillance cultures be performed in patients such as B.C.?

Neutropenic cancer patient with fever and/or other signs and symptoms of infection should undergo prompt risk assessment and initiation of antibiotic therapy. Once cultures are obtained, these patients should be emergently started on broad-spectrum antibacterials. Prompt institution should not be delayed if cultures cannot be obtained. Early studies confirmed high mortality in neutropenic patients with untreated gram-negative infections up to 24 to 48 hours after the onset of fever. Crude mortality rates secondary to P. aeruginosa bacteremia approached 91%.[6] Prompt use of empiric, broad-spectrum antibiotics has resulted in significant reductions in infectious mortality rates.

Initial Empiric Antibiotic Regimens

CASE 75-1, QUESTION 7: Should B.C. be started on antibiotic therapy immediately? Is this rational in view of the fact that neither the source of her fever nor the pathogen has been established?

Practice guidelines prepared by the National Comprehensive Cancer Network,[3] the Infectious Diseases Society of America,[4] and the European Society of Medical Oncology[14] identify antimicrobial options for the treatment of fever in the neutropenic cancer patient. The ideal antibiotic regimen for empiric management in this setting (i.e., those without evidence of site- or pathogen-specific infections) remains controversial. High-risk patients requiring IV therapy are often candidates for monotherapy regimens, including an antipseudomonal third-generation cephalosporin (e.g., ceftazidime), a fourth-generation cephalosporin (e.g., cefepime), or an antipseudomonal carbapenem (e.g., imipenem–cilastatin or meropenem).[3],[4,14,15] Initial, empiric use of additional antibiotics (such as fluoroquinolones, aminoglycosides, and vancomycin) may be added to patients who are clinically unstable.[4] Alternative initial empiric parenteral regimens (excluding those containing vancomycin) have been investigated in this patient population.[3],[4,14,15,34] However, because no significant differences exist among any of these empiric approaches, monotherapy is employed in most patients.

Optimal Antibacterial Spectrum

CASE 75-1, QUESTION 8: What pathogen- and patient-specific factors should be considered when initiating empiric therapy for B.C.?

Despite continued development in antibacterial drugs, the empiric management of febrile neutropenic patients is complicated by the changing spectrum of bacterial pathogens and their antimicrobial susceptibilities. Empiric antibiotic regimens should provide broad-spectrum coverage against the potential gram-negative bacilli most commonly isolated from neutropenic cancer patients (e.g., E. coli, K. pneumoniae, P. aeruginosa), staphylococci, and viridans streptococci.[3],[13] Because mortality from untreated bacteremia caused by P. aeruginosa is so high,[65]

---

empiric regimens have traditionally included antimicrobials with antipseudomonal activity.

Selecting an initial empiric regimen for a given patient should take into account the patient's risk of infection, likely pathogens, infection site-specific antibiotic efficacy, and institutional susceptibility patterns. This point is especially true in areas experiencing a growing frequency of multidrug-resistant organisms, such as MRSA, VRE, and extended-spectrum β-lactamase (ESBL)-producing organisms (such as K. pneumoniae and E. coli).[18] Patient-related considerations should include medical stability, allergies, prior and concomitant antimicrobials, and organ dysfunction (e.g., renal or hepatic). Attempts should be made to identify low-risk patients for whom oral antimicrobial therapy may be an option. Finally, dosing schedules, acquisition costs, and the potential for significant toxicities should be considered. In addition to broad-spectrum activity, antibacterial regimens should be bactericidal against the infecting pathogen. However, no adequately controlled comparative trials of bacteriostatic versus bactericidal antibiotics have been conducted in humans.

In summary, many organisms, including those recovered from surveillance cultures, may be pathogens in B.C. Those associated with a high mortality rate during the first 48 hours should be empirically treated pending culture and sensitivity results. Therefore, an empiric regimen with optimal activity against commonly isolated gram-negative bacilli (including P. aeruginosa) should be promptly administered to B.C.

ORAL ANTIBIOTICS

Carefully selected (i.e., low risk) adult febrile neutropenic patients may be candidates for oral antibiotic therapy, either as initial therapy or as follow-up to IV antibiotics (sequential therapy).[2],[4,106–108] Patients must be able to tolerate oral medications. In general, patients considered for oral therapy must be without microbiologic or clinical evidence of infection (other than fever), clinically stable, and closely observed. Patients with severe (ANC < 100 cells/μL), or lasting anticipated ≥7 days, or those receiving prior fluoroquinolone prophylaxis would not be eligible. This would also exclude patients with any of the following: serious comorbidities, inpatient acquisition of infection, uncontrolled malignancy, pneumonia, recent HSCT, dehydration, hypotension, chronic lung disease, abnormal liver (>3× upper limits of normal) or renal function (serum creatinine >2 mg/dL), or signs and symptoms lasting longer than 7 days.[4] An international collaborative study established and validated a risk scoring system in adults that incorporated these principles to identify low-risk patients for whom oral therapy may be an option.[33]

Cefixime has been used effectively as an alternative regimen in low-risk pediatric patients initially receiving IV therapy,[109] but there is not adequate experience to recommend it at this time. It also lacks activity against Pseudomonas spp. Fluoroquinolone-containing regimens have been the mainstay of most oral regimens used in this setting. Patients already receiving fluoroquinolones as prophylaxis should be excluded from receiving this regimen. Oral ciprofloxacin in combination with amoxicillin–clavulanate (both administered every 8 hours) is useful in low-risk adult patients with febrile neutropenia[110],[111] and is the most commonly used oral regimen. Oral levofloxacin may be used in place of ciprofloxacin, and oral clindamycin may be used in place of amoxicillin–clavulanate if the patient is allergic to β-lactam antibiotics. More recently, moxifloxacin has been evaluated in this patient population and demonstrates efficacy comparable to combination regimens containing ciprofloxacin.[112],[113] However, although moxifloxacin permits simplification of the regimen, it lacks activity against Pseudomonas spp. Therefore, its use should be restricted to patients at low risk of pseudomonal infections.

Low-risk patients with adequate home support (e.g., access to emergency facilities, phone access) and the desire for home treatment may be treated as an outpatient (with either IV or oral therapy). Therapy is usually initiated in a clinic or hospital setting.[4] Monitoring in the outpatient setting should include either home nursing or office visits daily for 3 days to review progress and to screen for problems. Patients who are stable and responding after the initial observation period may continue to receive monitoring by phone contact.

Continued administration of antimicrobials in the outpatient setting initiated as an inpatient has been suggested in a subset of low-risk patients. The criteria used to define eligibility for outpatient therapy are generally similar to those established and previously discussed for oral therapy. Therefore, continued outpatient administration of parenteral antibiotics can be considered in a subset of low-risk patients with close medical follow-up.[4]

INTRAVENOUS MONOTHERAPY

In general, intravenous monotherapy with an antipseudomonal β-lactam (such as an antipseudomonal cephalosporin, carbapenem, or β-lactam and β-lactamase combination) is advocated as initial empiric therapy for most neutropenic cancer patients.[3],[4] There are no convincing data to support one choice over the others as empiric monotherapy.

Antipseudomonal Cephalosporins

Ceftazidime monotherapy has been found to be as effective as combination therapy. However, in some of these trials, the efficacy of ceftazidime in patients with documented staphylococcal and streptococcal infections was suboptimal. Select clinical trials have empirically added antistaphylococcal coverage with a glycopeptide (e.g., vancomycin) and have shown improved outcomes in these patients. In addition, pathogens (particularly gram-negative pathogens) that produce either type 1 β-lactamase or ESBL (e.g., K. pneumoniae) are not likely to respond to ceftazidime monotherapy. These organisms are more likely with prolonged hospitalization or receipt of antimicrobial therapy. Therefore, local in vitro susceptibilities of common gram-negative pathogens should be examined before the routine use of ceftazidime as monotherapy.

Cefepime is a fourth-generation cephalosporin with an FDA-approved indication for monotherapy for empiric management of infection in patients with febrile neutropenia. The potential advantage of this agent compared with third-generation cephalosporins is its low affinity for major chromosomally mediated β-lactamases. Compared with ceftazidime, cefepime has more potent activity in vitro against select gram-positive bacteria (methicillin-susceptible Staphylococcus species, viridans streptococci, and S. pneumoniae). Similar to ceftazidime, numerous randomized, comparative studies have evaluated the role of cefepime as monotherapy in both adults and children with febrile neutropenia. The improved gram-positive activity (relative to ceftazidime) may decrease the empiric need for vancomycin in some patients. However, this advantage is less likely in institutions with a high rate of MRSA because cefepime and other cephalosporins (with the exception of ceftaroline) are inactive against this pathogen. Although a meta-analysis published in 2007 suggested increased all-cause mortality in neutropenic patients treated empirically with cefepime,[114],[115] subsequent analysis by the FDA concluded no such differences existed when compared with control patients.

Carbapenems

The carbapenems are a unique class of antibiotics with broad-spectrum activity against numerous gram-positive and gram-negative bacteria, including anaerobes. In addition, carbapenems may be used in the setting in which the patient is at increased risk of ESBL-producing gram-negative pathogens (such as K. pneumoniae or E. coli). Imipenem (in combination with the dehydropeptidase inhibitor cilastatin) and meropenem are two currently available agents in this class that have been studied as monotherapy for febrile neutropenic patients.

Clinical outcomes with imipenem–cilastatin monotherapy have been comparable with those of the β-lactam plus aminoglycoside combinations. Although effective, imipenem–cilastatin has generally been associated with a higher incidence of nausea and vomiting compared with ceftazidime or meropenem.[116],[117] The GI side effects are generally dose-related (3–4 g/day) and associated with the rate of IV administration. Therefore, dosages of 2 g/day (divided every 6 hours) are generally given to patients with normal renal function.

Meropenem monotherapy for febrile neutropenia has been evaluated in both adults and children, and the results have supported the value of meropenem as empiric monotherapy for use in febrile neutropenic patients. Meropenem may have advantages over imipenem–cilastatin in the treatment of central nervous system infections (owing to less associated seizure activity).

Although doripenem possesses comparable microbiologic activity, studies evaluating its administration in this population are lacking. Although ertapenem possesses microbiologic activity comparable to that of the other carbapenems, it lacks in vitro activity against Acinetobacter species and Pseudomonas spp., including P. aeruginosa. Considering this lack of activity, ertapenem would not be appropriate as empiric therapy for febrile neutropenic patients. Agents with increased anaerobic activity (including carbapenems) might be used as empiric therapy in cases in which an intra-abdominal infection is suspected.

Routine carbapenem use may be associated with increased drug acquisition cost (relative to cephalosporins) and increased potential for development of carbapenem resistance. Therefore, many institutions have elected to reserve the carbapenems for patients who have failed to respond to prior empiric therapy, have a history of infections with pathogens resistant to third- and fourth-generation cephalosporins, are clinically unstable, or have need for expanded anaerobic coverage.

β-Lactam/β-Lactamase Inhibitors

Randomized trials have compared piperacillin–tazobactam monotherapy to various antibiotics. Published trials have documented that piperacillin–tazobactam is not inferior to cefepime in this patient population.[118],[119] Although experience with this agent as monotherapy is limited relative to that for the antipseudomonal carbapenems and antipseudomonal cephalosporins, it is considered to be an adequate choice for monotherapy.[4] Higher doses of piperacillin–tazobactam (i.e., 3.375 g IV every 4 hours or 4.5 g IV every 6 hours in adult patients with normal renal function) should be used because of the risk of pseudomonal infections.[3] Piperacillin–tazobactam may interfere with the galactomannan assay used in the diagnosis of select IFIs, including aspergillosis.

INITIAL ANTIMICROBIAL COMBINATIONS (EXCLUDING VANCOMYCIN)

CASE 75-2

QUESTION 1: B.L., a 13-year-old boy, presented with a 3-week history of "always being tired" and a persistent sore throat. Initial evaluation revealed anemia, thrombocytopenia, and a WBC count of 130,000 cells/L, with a predominance of immature lymphoblasts. Further evaluation demonstrated that B.L. had high-risk acute lymphocytic leukemia. Remission induction treatment was initiated with teniposide plus cytarabine followed by prednisone, vincristine, and L-asparaginase. Seven days after induction chemotherapy, B.L. experienced a fever (102°F) and chills. The ANC was 48 cells/μL. SCr and BUN were 1.0 and 15 mg/dL, respectively. The physician wants to empirically start B.L. on ceftazidime plus gentamicin combination regimen. What is the role of this combination in the empiric management of febrile neutropenia? Are there any differences in efficacy between these combinations?

Before the introduction of third- and fourth-generation cephalosporins and carbapenems, the empiric use of antibacterial combinations in febrile neutropenic cancer patients was favored because these regimens offered a broader spectrum of activity against bacteria commonly infecting cancer patients.[3],[120] In addition, these combinations offered the potential for an additive or synergistic effect.[120],[121] However, infections in neutropenic patients have shifted largely from gram-negative to gram-positive pathogens, for which these traditional combination regimens have limited efficacy. Despite this concern, some clinicians continue to favor antibiotic combinations as initial empiric therapy, especially in patients who are clinically unstable.[3] It is unknown whether combination therapy prevents the emergence of resistance.

Until the 1980s, most febrile neutropenic patients were treated with two-drug combination regimens that contained an aminoglycoside (gentamicin, tobramycin, or amikacin) plus a β-lactam antibiotic, such as antipseudomonal penicillin, or an antipseudomonal third-generation cephalosporin. This combination is one of the most established empiric treatment regimens for the management of febrile neutropenia.

Numerous studies have been conducted to evaluate the efficacy of combination therapy of an aminoglycoside with an antipseudomonal cephalosporin (ceftazidime and cefepime).[3] Antipseudomonal penicillins plus β-lactamase inhibitors (in combination with an aminoglycoside) would also be considered a comparable regimen. A better outcome was demonstrated with full-course amikacin plus ceftazidime than with a short course (3 days) of amikacin plus a full course of ceftazidime.[122] However, the longer course of the aminoglycoside is likely to be associated with more toxicity.

Because carbapenem antibiotics are more frequently evaluated as monotherapy in this patient population, there are limited studies examining the combination of an aminoglycoside with either imipenem–cilastatin or meropenem. However, in one such evaluation, the combination of imipenem–cilastatin plus amikacin was found to be superior to imipenem–cilastatin monotherapy.[123] Carbapenems (in combination with aminoglycosides and vancomycin) have been recommended as empiric initial therapy for patients who are clinically unstable.

Aminoglycosides have generally been considered the backbone of combination regimens because of their potential for bactericidal action against various bacteria. However, the addition of an aminoglycoside is associated with increased costs for therapeutic monitoring. The benefit of an aminoglycoside for empiric therapy has not been consistently demonstrated.[123],[124] In addition, there is an increased potential for the development of nephrotoxicity and ototoxicity.[124] This concern is especially relevant in patients receiving concomitant nephrotoxins (such as cisplatin and cyclosporine).

CASE 75-2, QUESTION 2: Seven days into therapy, despite rehydration, B.L.'s SCr and BUN rose to 2.0 g/dL and 45 mg/dL, respectively. Because B.L. has nephrotoxicity (believed to be secondary to the aminoglycoside), what other combination regimens (excluding those containing aminoglycosides) could be used?

Are these regimens as effective as aminoglycoside-containing regimens?

As previously stated, ciprofloxacin has been studied in combination with other antibacterials (either an aminoglycoside or a β-lactam, including an antipseudomonal penicillin) as initial empiric therapy for treatment of suspected infection in febrile neutropenic patients.[3],[125–128] Ciprofloxacin in combination with clindamycin may also be useful in patients unable to receive β-lactam-containing combinations owing to the presence of immediate-type hypersensitivity reactions.[4] These studies, however, were associated with increased gram-positive infections in ciprofloxacin-treated

---

patients. In addition, the in vitro activity of ciprofloxacin against P. aeruginosa has declined significantly (to <70% in many institutions). Therefore, if used as part of combination therapy, ciprofloxacin should be combined with an antimicrobial with favorable in vitro activity against this pathogen. Alternatively, the combination of aztreonam and vancomycin has been recognized as reasonable empiric combination therapy in patients with immediate-type hypersensitivity reactions to penicillin.[4]

Use of initial empiric therapy with combination antibiotic therapy is generally reserved for patients who are clinically unstable (hypotension, tachycardia, tachypnea, mental status changes, etc.). In such settings, intravenous therapy with an antipseudomonal β-lactam is generally combined with an aminoglycoside and vancomycin. Systemic antifungals (such as fluconazole or an echinocandin) may also be added in such settings, especially in patients not receiving antifungal prophylaxis.

EMPIRIC VANCOMYCIN

CASE 75-2, QUESTION 3: B.L. is begun on a two-drug regimen of ceftazidime and vancomycin. What is the rationale for adding vancomycin to the regimen?

As previously discussed, gram-positive bacteria are important pathogens in these patients. Because cephalosporins lack activity against methicillin-resistant staphylococci, vancomycin is often added to empiric regimens. A growing proportion of S. aureus infections are methicillin resistant (as many as 60% in some institutions). However, widespread use of vancomycin may be one factor associated with the rise in vancomycin resistance among enterococci. Furthermore, vancomycin intermediate-resistant S. aureus and rare case reports of S. aureus fully resistant to vancomycin have been reported. Vancomycin use has also been associated with a modest increase in the incidence of nephrotoxicity.

Primarily because of differences in the measured endpoints, the need for vancomycin as initial empiric therapy continues to be debated.[129] For example, febrile neutropenic patients with cancer had more rapid resolution of fever, fewer days of bacteremia, and a lower frequency of treatment failure when vancomycin was added to an initial regimen of antipseudomonal penicillin plus an aminoglycoside.[130],[131] Similarly, the addition of vancomycin to ceftazidime showed improved results compared with ceftazidime alone or with a three-drug combination.[132] However, other studies have concluded that mortality was not increased when vancomycin therapy was delayed.[133–136] The mortality from staphylococcal (generally coagulase-negative staphylococci) infections is generally considered to be low (<4%) during the first 48 hours after the onset of fever. In contrast, the mortality associated with viridans streptococcal infections is higher among patients who are not initially treated with vancomycin.[137] Some strains of viridans streptococci are either resistant or tolerant to penicillin.[137],[138] In general, vancomycin would represent a reasonable alternative treatment of such infections, or in patients allergic to penicillins.

There continues to be considerable debate about whether vancomycin should be included in the initial empiric regimen for febrile neutropenic patients.[129] In general, routine use of empiric vancomycin should be discouraged.[3],[4] However, for institutions frequently isolating invasive gram-positive bacterial pathogens (e.g., those caused by viridans streptococci), vancomycin should be considered in the initial empiric regimen. In addition, patients at highest risk of serious, invasive infections with gram-positive organisms should be considered for initial vancomycin therapy. Such patients include suspected catheter-related infections, skin or soft-tissue infections, or pneumonia, those receiving intensive chemotherapy (e.g., high-dose cytarabine) resulting in substantial mucosal damage, patients receiving prior fluoroquinolone or TMP–SMX prophylaxis, those with prior history of colonization with β-lactam-resistant pneumococci or MRSA or with gram-positive bacteria in blood cultures (before identification and susceptibility testing), and those with sepsis without an identified pathogen should also be considered for vancomycin therapy.[4] The addition of vancomycin to an aminoglycoside-containing regimen should be done with caution because data support an increased risk of aminoglycoside-induced nephrotoxicity in patients receiving these agents concomitantly with vancomycin.[139] More recently, vancomycin has been shown to increase the risk of nephrotoxicity in patients receiving piperacillin–tazobactam.[8],[140–142]

Alternatives to Vancomycin with Activity Against Gram-positive Pathogens

Options exist for the treatment of invasive gram-positive infections. Linezolid is an oxazolidinone that can be administered IV or orally. A randomized, double-blind trial comparing the use of linezolid with vancomycin for empiric therapy demonstrated comparable safety and efficacy.[143] It is associated with thrombocytopenia and secondary neutropenia, especially when given for prolonged periods (i.e., >14 days according to the product's package insert). Considering the reduced bone marrow reserve in cancer chemotherapy patients, these adverse events are of particular concern. In addition, it is currently not recommended for patients with catheter-related infections (including bacteremia). The emergence of linezolid-resistant enterococci is of concern in this patient population. Therefore, its primary role in this patient population would be as a treatment for resistant or refractory gram-positive infections (such as MRSA or VRE). Tedizolid, an oxazolidinone for IV and oral therapy, has more recently been approved in the US. Although advantages over linezolid include a potential reduction in hematologic adverse events and drug interactions, data are lacking to support tedizolid use in this population. In addition, tedizolid is not currently recommended in patients with neutropenia.

Quinupristin–dalfopristin is available for IV administration only, and concerns about potential drug interactions and patient tolerability (including myalgias and arthralgias) limit its use as empiric therapy in this setting. Daptomycin provides potent in vitro activity against many multidrug-resistant gram-positive pathogens (including VRE and MRSA). Compared to historical controls treated with vancomycin, daptomycin use in cancer patients with gram-positive catheter-related bacteremia was associated with earlier and overall improved response.[144,145] Daptomycin requires IV therapy and should not be used for the treatment of pneumonia. Tigecycline possesses activity in vitro against both MRSA and VRE (in addition to many gram-negative and anaerobic pathogens). However, it lacks activity against P. aeruginosa and therefore would not be considered a viable option for empiric monotherapy. Telavancin is a new lipoglycopeptide with potent activity in vitro against select gram-positive pathogens (including MRSA). However, experience to date in this population has not been published. Ceftaroline is a cephalosporin with activity against MRSA recently approved for the treatment of complicated skin and skin structure infections and community-acquired pneumonia. However, reports of the use of ceftaroline in this patient population are sparse. In addition, ceftaroline has infrequently been associated with neutropenia, most notably at higher doses and/or for prolonged courses of therapy.[146–148] Data are also lacking for the use of oritavancin and dalbavancin (also recently approved for IV therapy of MRSA infections) in these patients. Therefore, these alternative agents (daptomycin and linezolid) are generally reserved for situations in which vancomycin is inappropriate (because of resistance or intolerance).[3,4]

In the case of B.L., empiric use of vancomycin is not warranted based on the previous discussion, and it should be discontinued unless cultures indicate the need for this antibiotic.

ANTIBIOTIC DOSING, ADMINISTRATION, AND

MONITORING CONSIDERATIONS

Intermittent versus Continuous versus Prolonged Infusion of Intravenous Antibiotics

CASE 75-2, QUESTION 4: Should B.L.'s antibiotics be given intermittently (i.e., divided doses) or as a continuous infusion?

β-Lactam antibiotics exhibit time-dependent (i.e., concentration-independent) pharmacodynamic activity, and in vitro models of infection suggest that prolonged exposure of bacteria to drug concentrations above the minimum inhibitory concentration is linked with improved bacterial killing and survival. On the basis of these observations and the poor prognosis of neutropenic cancer patients with bacteremia, noncomparative, open-label trials were conducted to evaluate the role of continuous infusions of β-lactams (i.e., ceftazidime) in the empiric treatment of suspected infection in cancer patients.[149–151] Additional studies in patients with febrile neutropenia have also been performed with meropenem suggesting a potential benefit of prolonged infusion over traditional administration.[152] However, this method of administration would require an IV line dedicated for continuous drug administration and limit B.L.'s ability to receive intermittent tobramycin infusions unless additional IV ports or lines are available for use. In contrast to continuous infusions, prolonged infusions (i.e., 3–4 hours) of select β-lactams (notably carbapenems, third- or fourth-generation cephalosporins, or piperacillin–tazobactam) have shown promise in a variety of pharmacodynamic models of infection (specifically with elevated minimum inhibitory concentrations) and tend to show better outcomes in observational studies. However, this has not been verified in prospective randomized, controlled trials. Prolonged infusions of β-lactams also have the potential to reduce the total dose and therefore result in drug acquisition cost savings. Although only limited clinical data exist to support such a strategy, such evaluations have not been tested specifically in the setting of infections in the neutropenic host.

Consolidated Interval (Extended-interval or "Once-daily") Aminoglycoside Dosing

CASE 75-2, QUESTION 5: What is the role of consolidated (once-daily) aminoglycoside dosing in febrile neutropenic patients such as B.L.?

Because of the concentration-dependent pharmacodynamic properties of aminoglycosides and the convenience of administration, studies have been conducted to describe both the pharmacokinetic properties and efficacy of consolidated dosing of aminoglycosides in animals and in neutropenic patients. Pharmacokinetic studies with amikacin[153,154] and gentamicin[155,156] have not revealed pharmacokinetic differences when compared with other populations. Several clinical studies have included consolidated aminoglycoside dosing for amikacin, gentamicin, and tobramycin.[157] However, most of the studies in this population were not designed to evaluate differences between consolidated aminoglycoside dosing compared with similar regimens using intermittent dosing. In general, the various studies suggest that consolidated dosing is as effective and possibly less nephrotoxic than traditional dosing. Therefore, consolidated dosing of aminoglycosides appears reasonable in empiric therapy of neutropenic patients.[157]

HOST FACTORS INFLUENCING RESPONSE TO THERAPY

CASE 75-2, QUESTION 6: What factors may have influenced B.L.'s clinical response to antimicrobial therapy?

The most important prognostic determinants of a favorable outcome in patients with neutropenia and infection are the recovery of the granulocyte count and (for the patient with infection) proper selection of antimicrobial therapy. Patients with profound, persistent neutropenia (<100 cells/μL that does not rise during therapy or an initial ANC of 100–500 cells/μL that declines during therapy) respond to antibiotics less favorably than patients whose bone marrow recovers. The initial granulocyte count appears to be less important than the trend toward granulocyte recovery. Although other evidence of bone marrow recovery (such as the absolute phagocyte count, absolute monocyte count, or reticulocyte fraction) may precede the ANC target of 500 cells/μL by several days, they are not as widely used clinically. The site of infection also influences outcome. Septic shock and pneumonia are associated with high mortality in bacteremic neutropenic patients.

MODIFYING INITIAL EMPIRIC ANTIBIOTIC THERAPY

CASE 75-3

QUESTION 1: M.H., a 24-year-old woman with a recent diagnosis of ovarian cancer, exhibited neutropenia (ANC <150 cells/μL) after chemotherapy. Five days after becoming neutropenic, she experienced a fever of 101°F and was begun on an empiric antibiotic regimen of ceftazidime 2 g IV every 8 hours. Although she remained febrile, her initial cultures remained negative at 48 hours. Should M.H. be continued on the same regimen, or should modifications be made? How do the culture results influence this decision? How long should empiric therapy be continued?

The need for modification of the initial empiric therapy is dependent on the risk group (i.e., low vs. high risk), establishment of an infection site or causative pathogen, response to initial therapy, and clinical stability. In the absence of worsening of clinical status or onset of new signs and symptoms of infection, 3 to 5 days of empiric treatment is generally required to determine initial efficacy after initiation of empiric antibiotics.[4] Defervescence in patients with hematologic malignancies, as well as HSCT recipients, may be delayed (up to 5 days). During this time, daily assessments should include history and physical examinations, review of laboratory results, assessment of response, and evaluation of any antibiotic-related toxicities. Adjustments to initial empiric antibiotic therapy should be made if a site-specific infection is identified, antimicrobial resistance is suspected or documented, or the patient's condition deteriorates.

Premature discontinuation of antibiotics may predispose these patients to recrudescence of bacterial infection and increase the risk of infection-related morbidity and mortality. Cancer patients with unexplained fever who became afebrile after empiric antibiotics

---

were randomly assigned to continue or discontinue antibiotic therapy after 7 days.[158] The patients whose neutropenia resolved had no infectious sequelae regardless of whether antibiotics were continued or discontinued. However, for persistently neutropenic patients randomly assigned to continue or discontinue antibiotic therapy until their ANC was greater than 500 cells/μL, the percentages of patients remaining febrile without infections complications were 94% and 41%, respectively. Therefore, initial empiric therapy in responding patients without an identified source should be continued until the patient's ANC is >500 cells/μL and increasing, and the patient is well and afebrile for at least 24 hours. Patients who are afebrile and stable but whose neutropenia persists may be considered for continuation with oral antibiotics (such as ciprofloxacin plus amoxicillin/clavulanate). Patients whose initial empiric regimen appropriately included vancomycin should continue receiving such therapy. In contrast, those initiated inappropriately on vancomycin, or in whom cultures, diagnosis or condition does not support continued use should have vancomycin therapy discontinued.

Documented Infections

CASE 75-3, QUESTION 2: On day 3, M.H.'s temperature is normal (97.6°C). However, two sets of blood cultures drawn 3 days ago have grown S. aureus resistant to methicillin and susceptible to vancomycin. Her ANC is 170 cells/μL. How should therapy be modified in M.H.? For how long should antibiotics be continued?

As previously stated, modification of initial empiric therapy should be made based on culture results as well as site-specific signs and symptoms of infection (Table 75-1). For example, anaerobic coverage (often with a carbapenem or piperacillin–tazobactam if not used for initial monotherapy) may be expanded in the setting of abdominal pain. Metronidazole or oral vancomycin should be initiated in the setting of diarrhea when C. difficile is suspected.[4] Vesicular lesions may be suggestive of viral infections (such as HSV or VZV) and may respond to the addition of acyclovir.[14] Suspected IV catheter infections should be managed with catheter removal (whenever possible), and this as well as skin and skin structure infections should be managed with treatment directed at MRSA.[4] For pneumonia, antibiotic coverage should be consistent with published guidelines for the treatment of health care-associated infections (see Chapter 67, Respiratory Tract Infections).[159] In the setting of severe or life-threatening pulmonary infections, antifungal therapy should also be included (see Table 75-1). Modifications of therapy may also be based on isolation of a resistant pathogen. For example, resistant gram-positive infections such as MRSA may be treated with vancomycin, linezolid, or daptomycin, whereas linezolid or daptomycin may be used for the treatment of VRE. For multidrug-resistant gram-negative pathogens, carbapenems are often used to treat ESBL-producing organisms, whereas carbapenemase-producing Enterobacteriaceae may require therapy with polymyxin, colistin, or tigecycline.

Table 75-1

Antibacterials in Patients with Neutropenia and Fever[a]

Condition	Therapy[b]
Initial Empiric Therapy (Site Unknown)	
Low Risk (Anticipated Neutropenia ≤7 Days, Clinically Stable, No Medical Comorbidities)	
Candidate for oral therapy	Adults: ciprofloxacin[a] + amoxicillin–clavulanate (alternate clindamycin if penicillin allergic), moxifloxacin Children: cefixime
Requires IV therapy	(see High Risk below)
High Risk (Anticipated Neutropenia >7 Days, Clinically Unstable, or Medical Comorbidities)	
	Piperacillin–tazobactam, antipseudomonal carbapenem,[c] ceftazidime, or cefepime Clinically unstable: consider addition of aminoglycoside, fluoroquinolone, or vancomycin to regimen above
Modifications of Initial Therapy	
Unexplained Fever	

Defervescence with negative cultures	Continue antibiotics Low-risk patients: if IV therapy initially, consider switch to oral therapy
Persistent fever (2–4 days) without clinical or microbiologic evidence of infection	Clinically stable: continue antibiotics
	Unstable: Hospitalize (if outpatient), IV therapy (if initially treated with oral), broaden antibacterial coverage to include anaerobes, resistant gram-negative rods, and resistant gram-positive organisms. Consider antifungal therapy for Candida species, or antimold therapy if previously receiving azole prophylaxis
	Consider empiric antifungal therapy on days 4–7, especially if neutropenia is expected to continue >7 days or the patient has other risk factors for fungal infections
	If initial regimen did not include vancomycin: re-evaluate risk factors for gram-positive infection, consider adding vancomycin
Documented Infection(s)	
Multidrug-resistant pathogen	MRSA: add vancomycin, linezolid or daptomycin[d] VRE: add linezolid or daptomycin ESBLs: switch to a carbapenem carbapenemase-producing Enterobacteriaceae: polymyxin-β-colistin or tigecycline
Head, Eyes, Ears, Nose, Throat	
Necrotizing ulceration	If initial regimen did not include anaerobic therapy (carbapenem or β-lactam/β-lactamase inhibitor; i.e., piperacillin–tazobactam), consider adding clindamycin or metronidazole or switch to antipseudomonal carbapenem (imipenem–cilastatin or meropenem) Consider adding antifungal or antiviral therapy for HSV
Oral vesicular lesions	Add antiviral therapy for HSV
Oral thrush	Add antifungal therapy (fluconazole) Consider extended-spectrum azoles (posaconazole, voriconazole) or an echinocandin if refractory to fluconazole
Esophagus	(See antifungal therapy for oral thrush) Consider acyclovir for HSV if laboratory or clinical suspicion of disease. Assess CMV risk and (if high) consider ganciclovir or foscarnet
Sinus tenderness, periorbital cellulitis, nasal ulceration	If suspicion of mold infection: add lipid-based formulation of amphotericin B. Reassess antistaphylococcal activity of empiric regimen; consider vancomycin Vancomycin for periorbital cellulitis
Gastrointestinal Tract	
Acute abdominal pain/perianal	If initial regimen did not include carbapenem or β-lactam/β-lactamase inhibitor (i.e., piperacillin–tazobactam), consider adding metronidazole, or switch to imipenem–cilastatin or meropenem. Assure pseudomonal coverage for perirectal infection For perirectal pain: consider enterococcal coverage for infection (not colonization) Consider antifungal
Diarrhea	Add metronidazole if Clostridium difficile documented or suspected. Oral vancomycin should be used for severe and/or complicated C. difficile infections. Contact isolation of rotavirus or norovirus documented
Respiratory Tract	
Pneumonia	Add fluoroquinolone or macrolide for atypical pathogens (Mycoplasma, Legionella). Add vancomycin or linezolid. (Note: daptomycin is NOT indicated for pneumonia due to inactivation by lung surfactant)

	For patients with additional (pathogen-specific) risk factors or clinical/lab evidence of infection: Consider the addition of a mold-active antifungal (seasonal) Consider oseltamivir against influenza PCP: institute TMP–SMX or (for sulfa-allergic patients) CMV: add ganciclovir if high risk Consider growth factors (G-CSF, GM-CSF)
Vesicular lesions	HSV, VZV treatment: acyclovir, famciclovir, or valacyclovir
Cellulitis, wound infection	Consider adding vancomycin (or alternative MRSA) therapy
Vascular access device infection, tunnel tract infection	Remove catheter whenever possible. Add empiric vancomycin (or alternative MRSA therapy). Adjust based on culture and susceptibility results
Central nervous system	Antipseudomonal β-lactam (cefepime, ceftazidime, or meropenem) + vancomycin. Add ampicillin if meropenem not used
Encephalitis	High-dose acyclovir
Urinary tract	Change based on pathogen identification and susceptibility
Bloodstream infections	Gram negative: add aminoglycoside and switch to antipseudomonal carbapenem Gram positive: add vancomycin, linezolid or daptomycin

[a] Exclude option if patient received fluoroquinolone prophylaxis.

[b] All modifications should be based on clinical and microbiologic data.

[c] Antipseudomonal carbapenem is imipenem–cilastatin or meropenem. Doripenem provides comparable in vitro activity, but has not been investigated in this patient population.

[d] daptomycin excluded for pneumonia.

CMV, cytomegalovirus; ESBL, extended-spectrum β-lactamase; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; HSV, herpes simplex virus; IV, intravenous; KPCs, Klebsiella producing carbapenemases; MRSA, methicillin-resistant Staphylococcus aureus; PCP, Pneumocystis jiroveci; TMP–SMX, trimethoprim–sulfamethoxazole; VRE, vancomycin-resistant enterococcus; VZV, varicella-zoster virus.

Clinical practice guideline for the use of antimicrobial agents in neutropenic patients with cancer: 2010 update by the Infectious Diseases Society of America. Clin Infect Dis. 2011;52:e56.

The duration of therapy is based on the infecting organism and site of infection (often up to 14 days), and should continue at least until the ANC is 500/μL or greater and rising.[4]

For patients with documented infections unresponsive to modification of therapy, new or worsening sites of infection should be suspected. Clinical, laboratory, and radiographic investigations should be undertaken or repeated. For hemodynamically unstable patients, antimicrobial therapy should be broadened and the patient should be considered for empiric antifungal therapy.[4]

No Etiology Identified

CASE 75-4

QUESTION 1: S.B. is a 55-year-old woman with chronic myelogenous leukemia. She was admitted to the hospital with a 4-day history of fevers and night sweats. On admission, her temperature was 102.3°F, and her WBC count was 100,000 cells/μL, with an ANC of 500 cells/μL. Blood and urine cultures were obtained, and cefepime was empirically started. For the next 3 days, S.B. remained persistently febrile and neutropenic. All cultures remained negative. How should she be treated?

Persistent fevers may be from noninfectious sources or from untreated infection. With the exception of consideration for antifungal therapy in some patients, those with persistent fever who are clinically stable do not routinely require a change in empiric therapy unless guided by clinical changes or culture results.[3],[4] However, outpatients with persistent fever should be hospitalized and receive IV therapy. Empiric addition of vancomycin in patients with persistent fever does not decrease the time to fever resolution in this population[160] and should therefore be discouraged.[4] In contrast, persistently febrile patients who are hemodynamically unstable without a clear source of infection should have their initial therapy modified to broaden coverage against resistant gram-positive and gram-negative organisms, as well as anaerobes.[3],[4] Patients with initial monotherapy with ceftazidime or cefepime can be switched to vancomycin with an antipseudomonal carbapenem (such as imipenem–cilastatin or meropenem) in combination with either an aminoglycoside, aztreonam, or ciprofloxacin.[3],[4] Antifungal therapy targeting Candida species should also be considered (see Case 75-4, Question 3).

CASE 75-4, QUESTION 2: S.B., on day 4, continues to feel "lousy" and has started to complain of abdominal pains. What is the significance of this complaint? Should her antibiotic regimen be modified again?

Because S.B. has new abdominal pains suggestive of enterocolitis, her antibiotic regimen should be modified. Although cefepime provides excellent coverage against the common gram-negative pathogens, it has limited activity against select gram-positive pathogens (e.g., MRSA or VRE) and anaerobes. A change from cefepime to imipenem–cilastatin or another broad-spectrum regimen with both aerobic and anaerobic activity should be considered.

CASE 75-4, QUESTION 3: S.B.'s antibiotic regimen was changed to imipenem–cilastatin. Despite the change, she continues to have a low-grade fever and does not feel better. What is S.B.'s risk for having a systemic fungal infection? What is the significance of fungal infections in neutropenic cancer patients?

ANTIFUNGAL THERAPY

Early diagnosis and prompt treatment of systemic fungal diseases are critical to patient survival. However, significant challenges exist in making an accurate and timely diagnosis of invasive fungal infections. Therefore, patients who are neutropenic with protracted (4–7 days) fever despite the administration of broad-spectrum antibiotics should be considered for empiric antifungal therapy, especially patients whose neutropenia is anticipated to exceed 7 days.[4],[161] Patients at highest risk of mold infections (i.e., those with prolonged neutropenia, allogeneic HSCT recipients, and/or those receiving high-dose corticosteroids) should be initiated on antifungals after 4 days of persistent fever unless they are currently receiving antimold prophylaxis. Considerations for earlier empiric antifungal therapy (i.e., days 2–4) should be made in patients with persistent fever and hemodynamic instability.[4]

Newer diagnostic tests (e.g., β-D-glucan tests or galactomannan assays), along with additional diagnostic support, may allow for early preemptive therapy (i.e., institution of therapy based on biomarker evidence of disease prior to the development of symptoms).[162] Such approaches may also be used to support decisions to withhold empiric antifungal therapy. As an example, persistently febrile patients on appropriate antibacterials who are clinically stable without clinical or radiographic signs of fungal infection have had negative serologic assays for invasive fungal infection and have had no recovery of fungi from any body site may have empiric antifungal agents withheld.[4],[104]

Considerations about the choice of empiric antifungals should include prior or current antifungal prophylaxis, risk of mold infections, risks of antifungal-related toxicities, drug interactions, route of administration, clinical stability, and costs.[23] It is difficult to compare data among clinical trials evaluating empiric antifungal therapy in neutropenic cancer patients because of differences in trial design. Such differences may include inclusion of low-risk patients, lack of blinding, changes in concomitant antibacterials obscuring antifungal therapy end points, prior antifungal prophylaxis, use of composite end points of safety and efficacy, and different endpoint criteria.[25] Although select studies have also demonstrated that empiric antifungal therapy can decrease fungal-related deaths, overall mortality has not been affected.[23] This is the case particularly for patients with invasive disease and persistent neutropenia.

In patients requiring therapy, antifungal coverage should be directed at Candida species. Highest-risk patients with persistent or recurrent fever after 4 to 7 days of appropriate antibacterial therapy and anticipated to have prolonged (i.e., >10 days) neutropenia should be considered for antimold therapy.[4]

CASE 75-4, QUESTION 4: Should amphotericin B or acyclovir therapy be considered in S.B.?

Historically, amphotericin B deoxycholate (AmBD) was most commonly used in this setting because of its reliable activity in vitro against most Candida and Aspergillus species. Comparative trials have also evaluated the role of lipid-based formulations of amphotericin B in the treatment of suspected or documented infections in this population. Liposomal amphotericin B (LAmB),[163–166] amphotericin B lipid complex,[165] and amphotericin B colloidal dispersion[167] have demonstrated reductions in nephrotoxicity compared with AmBD. In addition, LAmB is least likely to be associated with infusion-related side effects.[164] Although there are limited data to suggest that the continuous infusion of AmBD may also reduce nephrotoxicity,[168] efficacy regarding this method of administration in patients with documented infections has not been established. Therefore, continuous infusion of AmBD cannot be routinely recommended at this time. Considering the availability of other agents, empiric amphotericin B products are generally reserved for patients at highest risk of mold infections unable to receive alternative antifungals. When initiated as empiric therapy, amphotericin B administration is often preceded by attempts to minimize nephrotoxicity (e.g., saline loading) and premedications to minimize infusion-related reactions. Close monitoring of tolerability, renal function, and electrolytes is required during administration.

In stable patients at low risk of mold infections or drug-resistant Candida species (e.g., C. krusei and some strains of C. glabrata), fluconazole may be preferable to amphotericin B.[4,169,170] Patients with suspected mold infections (e.g., aspergillosis), hemodynamic instability, or in whom an azole was used as prophylaxis should not receive fluconazole. Although itraconazole possesses enhanced activity in vitro against Aspergillus species and has reduced toxicity relative to amphotericin B, issues regarding tolerability with the oral solution, erratic bioavailability with the capsule formulation, potential for cross-resistance with other azoles, lack of a parenteral treatment option, and considerations of alternative treatment options generally limit its usefulness. Posaconazole possesses a broad spectrum of activity in vitro against a variety of yeasts and molds. It is currently available in both an oral and intravenous formulation. Voriconazole (an azole antifungal agent with increased activity against Aspergillus and non-albicans Candida relative to fluconazole) has been tested in this population. When compared with LAmB, voriconazole failed to meet the pre-established criteria for noninferiority.[166] However, some believe that voriconazole should be considered as an alternative to amphotericin B preparations for empiric therapy in patients requiring initial empiric antifungal therapy who are at increased risk of mold infections (owing to receipt of prior azole prophylaxis) or for those patients suspected of having invasive candidiasis.[161] Because of the increased potential (relative to fluconazole) for drug interactions (including immunosuppressives and chemotherapy) and adverse events (e.g., phototoxicity, hepatotoxicity), voriconazole therapy should be monitored closely. IV use of voriconazole is contraindicated in patients with severe renal dysfunction. In addition, serum drug concentration monitoring for posaconazole and voriconazole may be considered in patients with suspected malabsorption.[4,9] Most recently, isavuconazole (a broad-spectrum, triazole antifungal) has been approved for both oral and IV administration for the treatment of invasive aspergillosis and mucormycosis.[171]

Potential advantages (relative to voriconazole) include improved oral bioavailability, predictable pharmacokinetics, and a reduction in the potential for drug interactions. For treatment of invasive aspergillosis, isavuconazole's efficacy was noninferior to that of voriconazole.

The echinocandins (e.g., caspofungin, micafungin, anidulafungin) possess in vitro activity against Candida species (including non-albicans Candida) and Aspergillus species. Caspofungin is at least as effective and better tolerated than LAmB as empiric therapy in this patient population.[172],[173] Because of their safety profile and in vitro activity, echinocandins are often considered for patients requiring initial empiric antifungal therapy and who are at increased risk of mold infections (owing to receipt of prior azole prophylaxis). Caspofungin is currently FDA approved for such use. Published experience with other echinocandins (e.g., micafungin, anidulafungin) as empiric therapy in the febrile neutropenic patient is lacking at present.

In summary, empiric antifungal therapy is indicated for persistent (4–7 days) or recurrent fever on appropriate antibacterials if the duration of neutropenia exceeds 7 days.[4] Low-risk patients who are clinically stable do not routinely need antifungal therapy.[4] Persistently febrile patients who are clinically stable without computed tomography signs of infection and have no serologic or culture results suggestive of infection may have antifungal therapy withheld.[4] Patients receiving fluconazole prophylaxis requiring addition of empiric antifungals should be considered for antifungals with activity against azole-resistant Candida species and mold infections.[4] In the setting in which an antimold agent was used for prophylaxis, switching antifungal classes or conversion to IV therapy should be performed.[4]

ANTIVIRAL THERAPY

Empiric use of antiviral agents in the febrile neutropenic patient is not indicated without evidence of such disease.[4] In contrast, clinical evidence of HSV or VZV involving the skin or mucous membranes should be treated with antivirals (e.g., acyclovir, valacyclovir).[4] When oral therapy is used, valacyclovir is generally favored over acyclovir because of improved oral bioavailability and need for less frequent dosing. With the exception of patients undergoing bone marrow transplantation,[174] CMV is an uncommon source of infection in the febrile neutropenic patient. However, ganciclovir, valganciclovir, foscarnet, or less commonly cidofovir treatment should be initiated in patients with documented CMV infections (antigenemia, polymerase chain reaction for CMV DNA, or detection of CMV mRNA). Because both ganciclovir and valganciclovir can cause or worsen existing neutropenia, caution and close monitoring is warranted when these agents are prescribed in this setting. Treatment with neuraminidase inhibitors (such as oseltamivir or zanamivir) may be initiated empirically for influenza in the setting of exposure or outbreaks if the patient is presenting with an influenza-like illness.[4] Likewise, if RSV is identified, appropriate antiviral therapy should be initiated.[4]

ANTIMICROBIAL ADJUVANTS

CASE 75-4, QUESTION 5: S.B. became afebrile 2 days after micafungin was initiated, yet she remained neutropenic with an ANC of 480 cells/µL. An induction chemotherapy regimen consisting of idarubicin plus cytarabine was initiated for her chronic myelogenous leukemia. Because the chemotherapy will further reduce her ANC 7 to 10 days after treatment, is there any way to facilitate marrow recovery and reduce the duration of neutropenia in S.B.?

As previously discussed, the duration of neutropenia is the most important factor affecting outcome in neutropenic cancer patients. Because of this, there has been considerable interest in enhancing the immune system in these patients.

Granulocyte Transfusions

One of the earliest approaches used to boost the patient's defense against infections was the transfusion of WBCs. In the 1970s, granulocyte transfusions were used adjunctively in patients with persistent neutropenia and documented infections who, despite appropriate antibiotics, failed to respond after 24 to 48 hours. This approach had limited value because of the difficulties in obtaining adequate cells for transfusion, as well as the problems with alloimmunization and risk of infection transmission. In addition, the questionable efficacy of WBC transfusions has decreased the use of this strategy.[175] Therefore, granulocyte transfusions are not routinely indicated in this population. However, patients with progressive bacterial or fungal infections unresponsive to appropriate antimicrobial therapy may be considered as candidates.[3]

Hematopoietic Growth Factors

Because these agents have not demonstrated a consistent and significant effect on other infection-related parameters (e.g., duration of fever, use of antibiotics, costs of treatment), the use of CSFs as adjunctive therapy to antibiotics for febrile neutropenic patients is controversial.[4],[31,83–85] Patients already receiving CSFs for primary or secondary prevention may be continued during treatment of febrile neutropenia.[84] Those patients administered pegfilgrastim for primary or secondary prevention should not require subsequent doses of CSFs due to persistence of high CSF concentrations for prolong periods.

Patients with high risks for infection-related complications not receiving CSFs for prophylaxis may be considered for therapy.[3],[85] Such risks include expected prolonged

(>7 days) and profound (<100 cells/µL) neutropenia in clinically unstable patients unresponsive to initial empiric therapy, age older than 65 years, uncontrolled malignancy, pneumonia, sepsis and multiorgan dysfunction (characteristic of sepsis syndrome), and invasive fungal infection.[84],[85]

Immunoglobulins

Data regarding the use of immunoglobulins as adjunctive therapy for the treatment of select infections in the neutropenic cancer patient are primarily limited to case reports. Patients with pneumonia secondary to CMV may benefit from adjunctive immunoglobulin therapy (in combination with ganciclovir). In addition, IV immunoglobulin G should be considered in those patients with hypogammaglobulinemia.

G-CSF administration, although likely to reduce the duration of her chemotherapy-induced neutropenia, is not indicated in S.B., who is otherwise stable.

Pharmacotherapy of Human Immunodeficiency Virus Infection

Jessica L. Adams and Mackenzie L. Cottrell

CORE PRINCIPLES

		CHAPTER CASES
①	Acute retroviral syndrome is characterized by nonspecific symptoms, such as fever, lymphadenopathy, rash, fatigue, and night sweats that coincide with an initial burst of viremia. These symptoms, as well as the presence of an opportunistic infection, and high-risk sexual or drug-using behaviors, warrant human immunodeficiency virus (HIV) testing. With current antigen/antibody laboratory tests, HIV can be diagnosed as early as 2 weeks after infection. In patients in whom very early infection (<2 weeks) is suspected, nucleic acid tests for HIV RNA may be considered for diagnostic purposes.	**Case 76-1 (Question 1)**
②	HIV RNA viral load is measured to quantify the level of viral replication in the body and CD4 cell counts are followed to assess immune system function.	**Case 76-1 (Question 2)**
③	Antiretroviral therapy should be offered to all patients who are willing and able to commit to lifelong treatment after a discussion of the benefits and risks of highly active antiretroviral therapy (HAART) and the importance of adherence. Clinical situations which favor more urgent initiation of HAART include pregnancy; AIDS-defining condition such as an opportunistic infection; CD4 count of <200 cells/μL; HIV-associated nephropathy (HIVAN); hepatitis B and/or C infection; rapidly declining CD4 count (>100 cells/μL decrease per year); higher baseline viral load (>100,000 copies/mL); and acute/early HIV infection. US Department of Health and Human Services (DHHS) guidelines provide recommendations for optimal antiretroviral therapy.	**Case 76-1 (Question 3)**
④	Goals of antiretroviral therapy include suppression of viral load, preservation and strengthening of the immune system, limitation of drug adverse events, promotion of adherence, and prevention of HIV-related morbidity and mortality.	**Case 76-1 (Question 4)**
⑤	General rules of therapy involve selection of HAART-based regimen, optimization of the selected agents, and inclusion of quality of life in decisions.	**Case 76-1 (Questions 5, 6)**
⑥	After initiating a HAART regimen, short-term goals include resolution of symptoms, at least a threefold (0.5 log) decrease in HIV RNA at 1 month, a tenfold decrease (1.0 log) in HIV RNA at 2 months, and an increase in CD4 count at 3 to 4 months. Long-term assessments include	**Case 76-1 (Questions 7, 8)**

	the monitoring of HIV RNA and CD4 count every 3 to 6 months to identify treatment failures, assessment of medication adherence, and determination of tolerability and quality of life.	
⑦	General rules for changing failing regimens include switching to at least two new active drugs (although all new drugs are preferable), as quickly as possible after treatment failure to avoid accumulation of resistance mutations. To avoid the development of further resistance, a single drug should never be added to a failing regimen. If one drug must be discontinued, the whole regimen should be stopped simultaneously. Finally, previously failed regimens should never be restarted because of the potential of archived resistance mutations.	**Case 76-1 (Questions 9, 10)**

⑧	Considerations for treatment of antiretroviral-experienced patients include regimen tolerability, comorbid conditions, associated pharmacokinetic properties, antiretroviral histories, and resistance testing. Resistance testing should be performed when HIV RNA is greater than 1,000 copies/mL. Antiretroviral drug resistance is assessed through two methods: genotyping evaluates mutations in the virus genetic code and phenotyping involves growing virus in various concentrations of drug to determine viral susceptibilities. DHHS guidelines provide recommendations for treating antiretroviral-experienced patients.	**Case 76-2 (Question 1–3)**
⑨	Drug interactions between antiretrovirals and coadministered medications are common and should always be screened with the addition of any new medication.	**Case 76-3 (Question 1)**
⑩	Antiretrovirals are used in pregnancy for the health of the mother and to prevent transmission of HIV to the child. There are specific DHHS guidelines for antiretroviral use in pregnancy.	**Case 76-4 (Question 1)**
⑪	The use of antiretrovirals for pre-exposure prophylaxis in individuals who are HIV negative, but at high risk for acquiring HIV, has been shown to be safe and effective in clinical studies. The combination product of emtricitabine/tenofovir disoproxil fumarate is FDA approved for this use, and the Centers for Disease Control and Prevention has issued guidelines on the use and monitoring of the combination for this indication.	**Case 76-5 (Question 1)**
⑫	The use of antiretrovirals for occupational (e.g., needle sticks) and nonoccupational (e.g., high-risk behaviors) postexposure prophylaxis (PEP) may be warranted if initiated within 48 hours but no longer than 72 hours after exposure. There are Centers for Disease Control and Prevention guideline recommendations for the choice of antiretrovirals for PEP.	**Case 76-6 (Question 1)**

INTRODUCTION

Potent combinations of antiretroviral drugs (also called highly active antiretroviral therapy [HAART]) have dramatically altered the natural progression of human immunodeficiency virus (HIV) infection, and significantly improved patients' quality of life. As a result, the number of newly acquired immunodeficiency syndrome (AIDS)-related opportunistic infections and deaths has declined.[1],[2] In most instances, the use of HAART has shifted HIV infection from a fatal disease to a manageable chronic disease. The most recent advances in HIV therapy include new and more potent antiretroviral agents in existing therapeutic drug classes, novel combinations of antiretrovirals, and new single tablet once daily regimens.

Despite the drastic improvements in HIV treatment over the last decade, successfully managing the HIV epidemic remains a challenge because of suboptimal patient compliance and the development of resistance, long-term adverse events, the price of antiretrovirals, and the rampant spread of HIV throughout resource-poor countries.

This chapter focuses on the antiretroviral treatment of HIV infection. Although many therapeutic options now exist, a thorough understanding of viral pathogenesis is essential for managing patients infected with HIV. By understanding the principles of therapy as they relate to viral pathogenesis, clinicians can rapidly assimilate new data as they become available. Consensus panel recommendations provide a framework for clinical decision making.[3–5] Given the complexity of therapy, this chapter focuses on treating adult HIV infections. A cursory introduction to the clinical concepts of perinatal transmission, pre-exposure prophylaxis (PrEP), and postexposure prophylaxis (PEP) for both occupational and nonoccupational HIV exposures are also provided. For more in-depth discussion of these concepts and the treatment of pediatric HIV, the reader is referred to the various consensus panel guidelines (http://www.aidsinfo.nih.gov/).

EPIDEMIOLOGY

Despite a dramatic decline in the number of AIDS-related opportunistic infections and deaths in industrialized countries,[2],[6] HIV infection remains in the top 10 leading causes of death worldwide.[7] Access to newer, more potent antiretroviral regimens and monitoring are often limited by economics and politics. Infected patients residing in countries with a strong economic standing (North America, Western Europe, Australia, and New Zealand) have reasonable access to medications, whereas patients residing in countries with scarce resources (Africa, south and southeast Asia, the Pacific, and the Caribbean) do not. This is of significant concern given that most infected patients worldwide reside in these latter regions of the world.[6]

As of 2016, the worldwide estimate of persons living with HIV infection was 36.7

million: 34.5 million adults (52% of which are women) and 2.1 million children younger than 15 years of age.[6] The estimated incidence (1.8 million new HIV infections) decreased by 18% from 2010, and the estimated number of AIDS-related deaths (1.0 million) decreased by 33%. Approximately, two-thirds (70%) of all HIV-infected adults and children live in Africa, and approximately three-quarters (72%) of all AIDS-related deaths occurred there in 2016. Increasing access to HIV treatment in this region has led to a 52% reduction in the number of AIDS-related deaths since 2001. Universal access to HAART became a global priority in 2000 when the United Nations Millennium Declaration called for unprecedented action to halt and begin to reverse the AIDS epidemic. This call to action resulted in an increase of more than 13 million persons living with HIV in Africa (~54%) accessing HAART in 2016 (increased from <1% in 2000). With these global efforts, the percentage of all HIV infected persons worldwide on HAART is 53%.

In the United States, the availability of antiretroviral therapy resulted in a drastic decline (67%) in AIDS-related death rates between 1994 and 2007, and this percentage continues to drop albeit at a slower rate (20% decline from 2009 to 2012). Despite

---

this success, 6,721 people in the United States still died from HIV attributable causes in 2014.[2] Racial and ethnic minorities continue to be disproportionately affected by HIV because of a complicated combination of poverty, disproportionate incarceration, and social and sexual network segregation.[8] In 2015 African Americans, who represented 12% of the US population, accounted for approximately 45% of all new HIV infections in adult and adolescents. Hispanics/Latinos, who constitute 18% of the U.S. population accounted for 24% of new infections in 2015. Compared with white men and women, the lifetime risk of HIV seroconversion is 6 times higher in African American men, 20 times higher in African American women, 3 times higher in Hispanic/Latino men, and 4 times higher in Hispanic/Latino women.[9] Transmission through sexual intercourse remains a predominant route of infection, with unprotected sex between men accounting for approximately 63% of cases, and heterosexual intercourse accounting for approximately 25% of cases in the United States.[9]

PATHOPHYSIOLOGY

Infection with HIV can be acquired through unprotected sexual intercourse (both anal and vaginal), injectable drug use, receipt of tainted blood products, and mother-to-infant transmission (both perinatal infection and postpartum through breast-feeding).[3]

Infection can also be acquired from occupational exposures among health care workers after needle sticks or infected blood splashes from patients infected with HIV onto vulnerable mucosal membranes. Rarely, HIV infection has been documented following oral sex.[10],[11]

Unprotected sexual intercourse accounts for approximately 80% of all documented HIV infections to date.[2],[6] Transmission between sexual partners depends on a number of factors, including the HIV viral subtype, stage of infection in the index partner, genetic susceptibility to infection of the potential host, and the viral fitness (or pathogenicity) of the infecting strain. Perhaps one of the most important predictors of transmission is the amount of HIV RNA in the blood of the infected index patient (i.e., viral load). Recently, initiation of HAART treatment and subsequently suppressing infected patients' viral loads has been shown to decrease transmission rates by >95% among serodiscordant couples where one partner is HIV infected and the other is not.[12] Infectivity via receptive anal intercourse represents the greatest sexual risk factor followed by male-to-female vaginal transmission and then female-to-male penile transmission.[13]

During transmission, HIV binds to specific immune cells, including Langerhans cells, dendritic cells, T-cell lymphocytes (also known as $CD4^+$ T cells, helper T cells, or T cells), and macrophages.[13–16] However, recent reports indicate that the initial virus propagated during early infection (the HIV-1 transmitted founder virus) may not replicate efficiently in monocyte-derived macrophages raising questions regarding the importance of macrophages in initial transmission events.[17] HIV primarily enters target immune cells that express specific receptor proteins known as CD4 receptors to which HIV binds. However, evidence indicates that for some cells types like Langerhans cells compensatory mechanisms for viral entry exist.[18] Once bound to the CD4 receptor, co-receptor proteins (CCR5, CXCR-4) are required for fusion of the viral membrane to the immune cell membrane.[19],[20] CCR5 co-receptors are found on both monocytes and T lymphocytes and are more abundant in patients newly infected with HIV.[21],[22] CXCR-4 co-receptors are predominantly found on T lymphocytes and are more abundant in patients who have been on long-term antiretroviral therapy. The CD4–co-receptor complex causes conformational changes to key HIV proteins (gp41 and gp120) allowing for a more close association between the virus and the host cell.[22],[23] HIV fuses with the cell and releases its contents into the host cell's cytoplasm: this includes the virus's RNA and specific enzymes necessary for replication (Fig. 76-1; see online animated images of HIV lifecycle and where the drugs act at http://biosingularity.wordpress.com/2007/03/04/3d-animation-of-hiv-replication/). The single-stranded viral RNA is transcribed via reverse transcriptase into a double-stranded proviral DNA that is subsequently incorporated into the host cell's genetic material via the integrase enzyme. HIV then uses the infected cell's machinery to translate, transcribe, and produce immature viral particles that bud and break from the infected cell. For these immature virions to become infectious, the HIV protease enzyme must cleave large precursor polypeptides into functional proteins.[24],[25] Once complete, the mature virion is free to infect new host cells and subsequently produce more infectious virus.

Over time, HIV-infected host cells can be destroyed by a number of mechanisms: (a) a direct cytolytic effect of the virus (e.g., formation of syncytium induction, cellular dysfunction); (b) the identification and elimination of the infected cell by the host's immune response (e.g., via cytotoxic T-cell lymphocytes); or (c) the cell's natural life cycle coming to completion.[26] In addition, HIV infection can inhibit the production of new CD4$^+$ cells.[27]

Once a patient becomes infected, an initial burst of viremia occurs and causes latent infection in various tissues (e.g., lymph nodes) and cells (CD4, macrophages, and monocytes).[26],[28] Most infectious HIV virions (~99%) reside inside lymph nodes and other immune-cell rich tissues found throughout the body.[14],[26],[29],[30] The immune system reacts by producing antibodies against HIV; however, given the rapid production of new HIV particles and the development of many new and genetically diverse viral strains (a result of the error-prone HIV reverse transcriptase), the antibody response is inadequate.[31] After this burst of viremia, a transient depletion of CD4$^+$ cells occurs (Fig. 76-2). Initially, patients may complain of nonspecific symptoms, such as fever, lymphadenopathy, rash, fatigue, and night sweats.[3]

This phase of infection is known as the acute retroviral syndrome.

In most cases, patients are unaware that they are infected. Within 6 months, the host's immune response is able to control the infection to a point where the number of virus particles produced per day equals the number of particles destroyed per day. This steady-state is often referred to as the patient's viral "set point."

The higher a patient's viral set point, the greater the risk for disease progression. This is because there is a greater chance for more widespread viral infection and immune cell destruction with a larger replicating viral population. Why some patients establish higher or lower viral set points is currently under investigation, but this may be a consequence of differences in immune responses, cellular receptor populations, viral subtypes, viral fitness, or a combination of these factors. This understanding of viral pathogenesis has led to a new paradigm of therapy that prioritizes initiating HAART in the acute phase of infection[3] to lower viral set points and reduce the size of the viral reservoir (i.e., long-lived, latently infected memory T cells believed to be responsible for repopulating the virus in infected patients who stop HAART). A significant challenge is to identify these patients with acute infection who have nonspecific symptoms.[32]

Once the initial burst of viremia has been controlled and the viral set point established, infection with HIV results in a constant battle between viral replication and suppression of that replication by the immune system. Mathematical models have calculated the production of HIV at 10 billion particles per day.[14],[33–35] To keep the infection controlled, the body must produce an equal immune response. Over time, HIV depletes the body of T cells, which places the host at an increased risk for opportunistic infections. Direct measurements of HIV RNA concentrations in plasma (also called "viral load") can predict disease progression (see subsequent discussion).[36–38] Higher viral load measurements represent an inability of the host to control viral replication, and a greater risk for immune cell destruction. Long-term "nonprogressors" (e.g., patients with asymptomatic HIV infection for >10 years; 5% of all HIV-infected patients) consistently have lower baseline viral loads than patients with rapidly progressive disease (e.g., AIDS within 5 years of infection; 20% of all HIV-infected patients).[39],[40]

Figure 76-1 Schematic representation of the HIV-1 life cycle. Five classes of antiretroviral drugs are available at present. CCR5 antagonists and fusion inhibitors inhibit the entry of virions into a new target cell. The step of reverse transcription can be targeted, using nucleoside nucleotide analogs or non-nucleoside reverse-transcriptase inhibitors (NRTIs, NtRTI, and NNRTIs, respectively). The class of integrase inhibitors prevents integration of viral DNA into host cell DNA. The class of protease inhibitors interferes with the last state of the life cycle, the proteolytic processing of the viral proteins, which results in the production of noninfectious particles. (Adapted from education materials provided by the National Institutes of Health available on AIDSinfo.nih.gov.)

Without intervention, the natural progression of HIV infection results in depletion of 50 to 100 T cells/μL/year.[26] The severity of immune dysfunction, as evidenced by T-cell loss, is highly predictive of the potential for the development of specific types of opportunistic infections. For example, Pneumocystis jirovecii pneumonia rarely occurs when T-cell counts are greater than 200 cells/μL, whereas retinitis from cytomegalovirus infection rarely occurs in patients with CD4 counts greater than 75 cells/μL. The diagnosis of AIDS is made when a significant amount of immune deterioration has occurred, either by depletion of $CD4^+$ cells to less than 200 cells/μL or because of the development of new opportunistic infections (Tables 76-1 and 76-2). It is important to recognize that not every patient with HIV has a diagnosis of AIDS. On average, without appropriate drug therapy, death occurs within 10 to 15 years after infection.[26]

The interplay between viral load and CD4 T-cell counts is often compared with that of a train heading toward a particular destination. If the destination is immune system destruction (and eventually death), then the T-cell count is the distance of the train from this destination, and the viral load (concentration of HIV RNA in plasma) is the speed of the train. As both higher speeds and shorter distances reach destinations faster, so does a high viral load and low T-cell count result in quicker onset of immune destruction (and death). Potent antiretroviral regimens decrease viral replication and dramatically alter the natural course of infection by prolonging the time to opportunistic infection and death.[41]

PHARMACOTHERAPY

Pharmacotherapy of HIV has been directed at inhibiting key areas of the HIV life cycle (Fig. 76-1 and animations found at http://biosingularity.wordpress.com/2007/03/04/3d-animation-of-hiv-replication/; Table 76-3). Nucleoside RT inhibitors (NRTIs) include zidovudine, didanosine, lamivudine, abacavir, emtricitabine, and stavudine, while nucleotide RT inhibitors currently only include tenofovir. These agents inhibit this enzyme by incorporating false nucleic acids into the newly forming proviral DNA.[42] This results in an HIV DNA strand that cannot continue to elongate. Non-nucleoside reverse transcriptase inhibitors (NNRTIs; nevirapine, efavirenz, rilpivirine, and etravirine) inhibit reverse transcriptase by directly binding to the enzyme itself and prevent DNA transcription from RNA.[43] Protease inhibitors (PIs: saquinavir, fosamprenavir, nelfinavir, indinavir, lopinavir, atazanavir, ritonavir, tipranavir, and darunavir) directly bind to the catalytic site of HIV protease, inactivating the enzyme and preventing maturation of the HIV virion.[44],[45] Unlike reverse transcription, which occurs early in the course of the HIV life cycle, protease enzyme activity occurs late in virion development. As a result, inactivation of the protease enzyme inhibits viral replication in any infected cell regardless of the current stage of HIV replication within that cell. In contrast, reverse transcriptase inhibitors can protect newly infected cells from becoming latently infected cells before the formation and insertion of proviral DNA into the host cell’s genetic material. However, these agents provide no benefit for those infected cells that are actively producing new strains of virus.

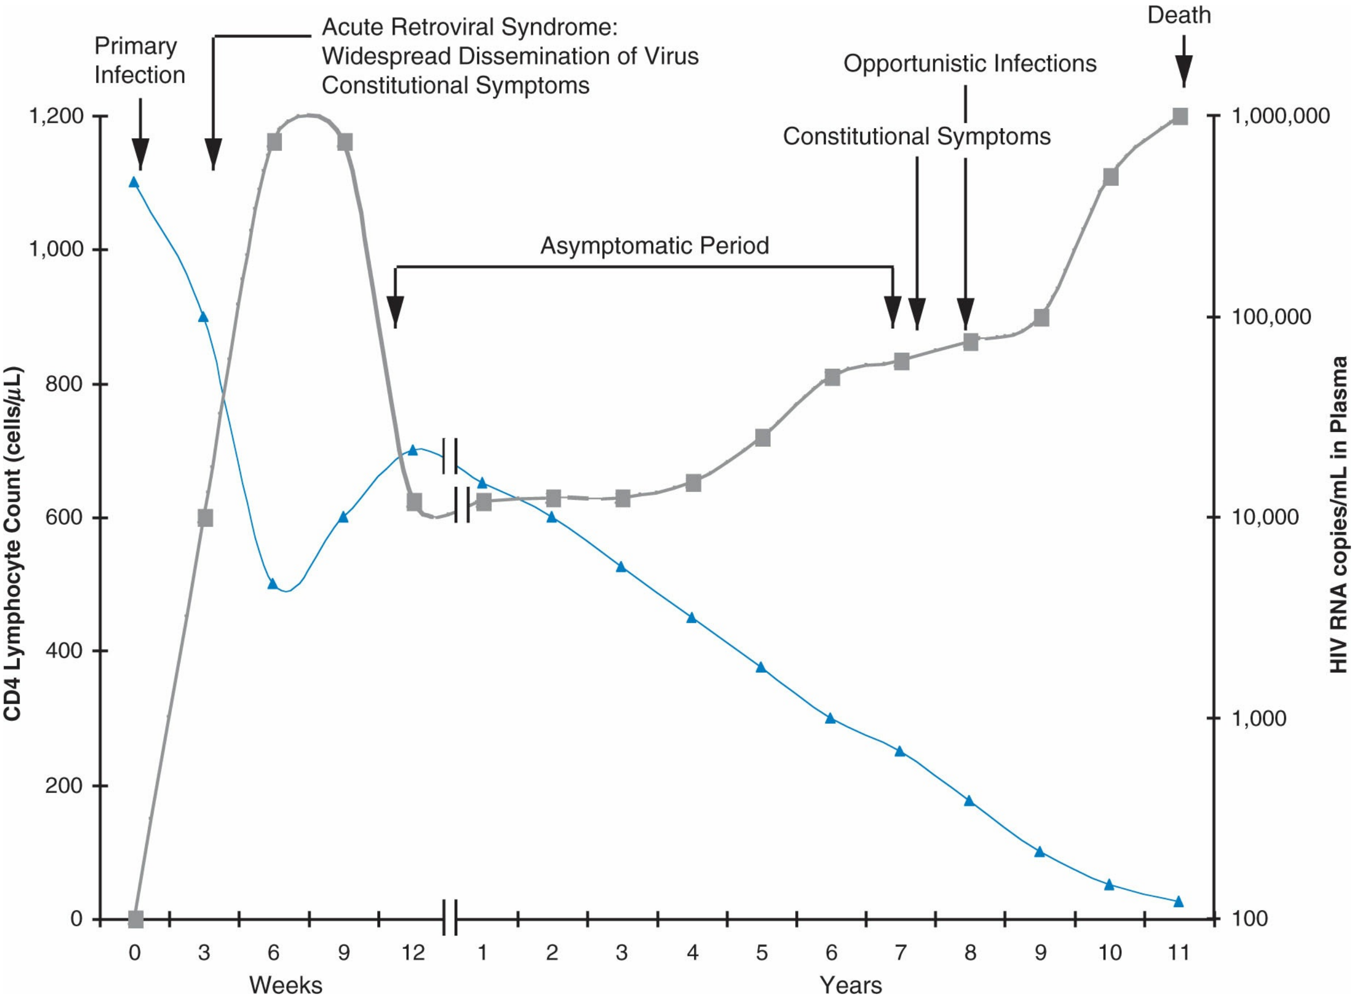

Figure 76-2 Sample disease course for an untreated HIV-infected individual showing the relationships among immunologic, virologic, and clinical outcomes over time. Constitutional symptoms include fever, night sweats, and weight loss. Viral load values; CD4 T lymphocytes. (Source: Fauci AS et al. Immunopathogenic mechanisms of HIV infection. Ann Intern Med. 1996;124:654; Perelson AS et al. HIV-1 dynamics in vivo: virion clearance rate, infected cell life-span, and viral generation time. Science. 1996;271:1582.)

Table 76-1

CDC MMWR Revised Surveillance Case Definition for HIV Infection—United States, 2014

HIV-infection stage[a] based on age-specific CD4$^+$ T-lymphocyte count or CD4$^+$ T-lymphocyte percentage of total lymphocytes						
	Age on date of CD4+ T-lymphocyte test					
	<1 year		**1–5 years**		**≤6 years**	

Stage	Cells/µL	%	Cells/µL	%	Cells/µL	%
0[b]	Staging independent of CD4 count/% and age					
1	≥1,500	≥34	≥1,000	≥30	≥500	≥26
2	750–1,499	26–33	500–999	22–29	200–499	14–25
3	<750	<26	<500	<22	<200	<14

[a] Stage is based first on the CD4$^+$ T-lymphocyte count then on percentage if the count is unavailable. Three situations can dictate that staging is not based on count or percentage: (1) Stage 0 criteria are met meaning that the stage is 0 regardless of CD4$^+$ T-lymphocyte test results and the diagnosis of opportunistic infection; (2) if the criteria for stage 0 are not met and a stage-3 defining opportunistic illness has been diagnosed (see Table 76-2), meaning that the stage is 3 regardless of CD4$^+$ T-lymphocyte test results; or (3) if the criteria for stage 0 are not met and information on the above criteria for other stages is missing, then the stage is classified as unknown.

[b] Stage 0 can be established either:

1. Based on testing history (previous negative/indeterminate test results): a negative or indeterminate HIV test (antibody, combination antigen/antibody, or NAT) result within 180 days before the first confirmed positive HIV test result of any type. The first positive test result could be any time before the positive supplemental test result that confirms it or
2. Based on a testing algorithm: a sequence of tests performed as part of a laboratory testing algorithm that demonstrate the presence of HIV-specific viral markers such as p24 antigen or nucleic acid (RNA or DNA) 0 to 180 days before or after an antibody test that had a negative or indeterminate result.

Table 76-2

CDC MMWR Revised Surveillance Case Definition for HIV Infection—United States, 2014. Appendix Stage-3 Defining Opportunistic Illnesses in HIV Infection

Bacterial infections, multiple or recurrent[a]
Candidiasis of bronchi, trachea, or lungs
Candidiasis of esophagus
Cervical cancer, invasive[b]
Coccidioidomycosis, disseminated or extrapulmonary
Cryptococcosis, extrapulmonary
Cryptosporidiosis, chronic intestinal (>1 month's duration)
Cytomegalovirus disease (other than liver, spleen, or nodes), onset at age >1 month
Cytomegalovirus retinitis (with loss of vision)
Encephalopathy attributed to HIV[c]
Herpes simplex: chronic ulcers (>1 month's duration) or bronchitis, pneumonitis, or esophagitis (onset at age >1 month)
Histoplasmosis, disseminated or extrapulmonary
Isosporiasis, chronic intestinal (>1 month's duration)

Kaposi sarcoma
Lymphoma, Burkitt (or equivalent term)
Lymphoma, immunoblastic (or equivalent term)
Lymphoma, primary, of brain
Mycobacterium avium complex or Mycobacterium kansasii, disseminated or extrapulmonary
Mycobacterium tuberculosis of any site, pulmonary[b], disseminated or extrapulmonary
Mycobacterium, other species or unidentified species, disseminated or extrapulmonary
Pneumocystis jirovecii (previously known as Pneumocystis carinii) pneumonia
Pneumonia, recurrent[b]
Progressive multifocal leukoencephalopathy
Salmonella septicemia, recurrent
Toxoplasmosis of brain, onset at age >1 month
Wasting syndrome attributed to HIV[c]

[a] Only among children aged <6 years.

[b] Only among adults, adolescents, and children aged ≥6 years.

[c] Suggested diagnostic criteria for these illnesses, which might be particularly important for HIV encephalopathy and HIV wasting syndrome, are described in the following references: CDC. 1994 Revised classification system for human immunodeficiency virus infection in children less than 13 years of age. MMWR. 1994;43(RR-12):1–10; CDC. 1993 Revised classification system for HIV infection and expanded surveillance case definition for AIDS among adolescents and adults. MMWR Recomm Rep. 1992;41(RR-17)1–19.

Adapted from **http://www.cdc.gov/mmwr/preview/mmwrhtml/rr6303a1.htm**.

Fusion inhibitors, such as enfuvirtide, prevent HIV and CD4$^+$ T cells from being pulled closer together after HIV binds to CD4 and CCR5 or CXCR-4 co-receptors. Enfuvirtide prevents fusion of the virus with the T-cell by binding to a double coil–coil complex at the gp41–gp120–CD4 receptor area.[46] The newest classes of antiretroviral agents are co-receptor blockers and integrase inhibitors. Maraviroc is a CCR5 co-receptor blocker which prevents HIV from fully binding to cells and causing infection.[47] Integrase strand transfer inhibitors (INSTIs: raltegravir, dolutegravir, and elvitegravir) prevent the integrase enzyme from integrating HIV DNA into the immune cell's genome.[48] The final class of agents used for HIV treatment, pharmacokinetic enhancers, are drugs that strongly inhibit CYP3A4, a liver enzyme responsible for metabolizing several PIs, NNRTIs, and INSTIs.[49] These agents are used with certain PIs and elvitegravir to impede metabolism and increase serum drug concentrations in order to decrease dosing requirements. Ritonavir, a PI itself, is now used primarily for its boosting effect rather than its anti-HIV activity. The newest pharmacokinetic enhancer, cobicistat, does not directly affect HIV replication.

With the development of newer, more potent antiretroviral regimens, researchers have speculated about the possibility of complete eradication of HIV from an infected patient. This outcome may require complete inhibition of viral replication in all cells and body stores where HIV resides.[13] However, a barrier to eradication is the varying half-lives of cell populations (e.g., 1–2 days for peripheral T cells vs. 14 days for macrophages).[50,51] In addition, extremely long-lived infected T cells with half-lives lasting more than 6 to 44 months have been identified.[52,53] Thus, it may require complete suppression of HIV replication for 60 years or more to eradicate HIV infection completely from the body.[52–54] Another complicating factor is the potential for HIV to reside in sites that achieve low antiretroviral concentrations, thereby serving as sanctuaries for HIV replication (e.g., central nervous system [CNS], testes). Once therapy is discontinued, these sites could theoretically release unaffected virions and repopulate the host. As a result, research has shifted toward immune-based therapies that can identify and destroy HIV-infected cells, in addition to preventing HIV acquisition.

Table 76-3

Characteristics of Antiretroviral Agents for the Treatment of Adult Human Immunodeficiency Virus Infection[3,5]

Drug	Dose	Pharmacokinetic Parameters	Administration Considerations
Nucleoside Reverse Transcriptase Inhibitors			
Abacavir (ABC) **Ziagen** Preparations Tablets: 300 mg Oral solution: 20 mg/mL Epzicom: ABC 600 mg + 3TC 300 mg Trizivir: ABC 300 mg + ZDV 300 mg + 3TC 150 mg Triumeq: ABC 600 mg + 3TC 300 mg + DTG 50 mg	300 mg every 12 hours, or 600 mg daily Epzicom: one tablet daily Trizivir: one tablet BID Triumeq: one tablet daily	Oral bioavailability: 83% Serum $t_{1/2}$: 1.5 hours Intracellular $t_{1/2}$: 12–26 hours Elimination: alcohol dehydrogenase and glucuronyltransferase; 82% renal elimination of metabolites	Can be administered without regard to meals Alcohol raises abacavir exposure by 41% HLA testing required before administration
Lamivudine (3TC) **Epivir** Preparations Tablets: 150, 300 mg Solution: 10 mg/mL Combivir: 3TC 150 mg + ZDV 300 mg	150 mg PO BID or 300 mg PO daily Combivir: one tablet BID Epzicom: one tablet BID Trizivir: one tablet BID Triumeq: one tablet daily	Oral bioavailability: 86% Serum $t_{1/2}$: 5–7 hours Intracellular $t_{1/2}$: 18–22 hours Elimination: 70% unchanged in urine	Can be administered without regard to meals

Epzicom: 3TC 300 mg + ABC 600 mg Trizivir: 3TC 150 mg + ZDV 300 mg + ABC 300 mg Triumeq: ABC 600 mg + 3TC 300 mg + DTG 50 mg			
Emtricitabine (FTC) Emtriva Preparations Capsules: 200 mg Oral solution: 10 mg/mL Truvada: FTC 200 mg + TDF 300 mg Atripla: FTC 200 mg + TDF 300 mg + EFV 600 mg Complera: FTC 200 mg + RPV 25 mg + TDF 300 mg Stribild: FTC 200 mg + EVG/c 150/150 mg + TDF 300 mg Descovy: FTC 200 mg + TAF 300 mg Odefsey: FTC 200 mg + RPV 25 mg + TAF 25 mg Genvoya: FTC 200 mg + EVG/c 150/150 mg + TAF 10 mg	200 mg daily for patients with calculated CrCl >50 mL/minute Dose needs to be adjusted for renal dysfunction: CrCl 30–49 mL/minute: 200 mg every 48 hours CrCl 15–29 mL/minute: 200 mg every 72 hours CrCl <15 mL/minute: 200 mg every 96 hours Truvada: one tablet daily. Not for patients with CrCl <30 mL/minute Atripla: one tablet daily. Not for patients with CrCl <50 mL/minute Complera: one tablet daily Stribild: one tablet daily. Not for patients with CrCl <70 mL/minute Stribild: one tablet daily. Not for patients with CrCl <70 mL/minute	Oral bioavailability: 93% Serum $t_{1/2}$: 10 hours Intracellular $t_{1/2}$: >20 hours Elimination: 86% recovered in urine	Can be administered without regard to meals
Tenofovir Disoproxil Fumarate (TDF) **Viread** Preparations Tablets: 150, 200, 250, 300 mg Oral powder: 40 mg/g Truvada: TDF 300 mg + FTC 200 mg Atripla: TDF 300 mg + FTC 200 mg + EFV 600 mg Complera: FTC 200 mg + RPV 25 mg + TDF 300 mg Stribild: FTC 200 mg + EVG/c 150/150 mg + TDF 300 mg	300 mg daily for patients with CrCl >60 mL/minute Truvada: one tablet daily. Not for patients with CrCl <30 mL/minute Atripla: one tablet daily. Not for patients with CrCl <50 mL/minute Complera: one tablet daily Stribild: one tablet daily. Not for patients with CrCl <70 mL/minute	Oral bioavailability: 25% fasting; 39% with high-fat meal Serum $t_{1/2}$: 17 hours Intracellular $t_{1/2}$: >60 hours Elimination: primarily by glomerular filtration and active tubular secretion	Can be administered without regard to meals
Non-Preferred Nucleoside Reverse Transcriptase Inhibitors			
Tenofovir alafenamide (TAF) Preparations	25 mg for patients with CrCl >30 mL/min	Oral Bioavailability: 40%	Can be administered without regard to

Descovy: TAF 25 mg + FTC 200 mg Odefsey: FTC 200 mg + RPV 25 mg + TAF 25 mg Genvoya: FTC 200 mg + EVG/c 150/150 mg + TAF 10 mg	Descovy: one tablet daily Odefsey: one tablet daily Genvoya: one tablet daily	Serum $t_{1/2}$: 0.51 hours Intracellular $t_{1/2}$: 150-180 hours Elimination: primarily by glomerular filtration and active tubular secretion	meals
Zidovudine (ZDV) **Retrovir (R)** Preparations Oral Solution: 10 mg/mL Capsule: 100 mg Tablet: 300 mg IV Solution: 10 mg/mL Combivir: ZDV 300 mg + 3TC 150 mg Trizivir: ZDV 300 mg + 3TC 150 mg + ABC 300 mg	300 mg BID or 200 mg TID Combivir (R) or Trizivir (R): one tablet BID	Oral bioavailability: 60% Serum $t_{1/2}$: 1.1 hours Intracellular $t_{1/2}$: 3 hours Elimination: hepatic glucuronidation; renal excretion of glucuronide metabolite	Can be administered without regard to meals (manufacturer recommends administration 30 minutes before or 1 hour after a meal)
Didanosine (ddI) **Videx** Preparations Videx EC (R): 125, 200, 250, 400 mg capsule Pediatric powder for oral solution (when reconstituted as solution containing antacid): 10 mg/mL Generic ddI enteric-coated capsule also available	>60 kg: 400 mg daily (with TDF, use 250 mg daily) <60 kg: 250 mg daily (with TDF, use 200 mg daily)	Oral bioavailability: 30%–40% Serum $t_{1/2}$: 1.6 hours Intracellular $t_{1/2}$: 25–40 hours Elimination: renal excretion ~50%	Food decreases absorption (↓ 55%); administer ddI on empty stomach (1 hour before or 2 hours after meal) Separate ATV and TPV/r administration by at least 2 hours
Stavudine (d4T) **Zerit** Preparations Solution: 1 mg/mL Capsules: 15, 20, 30, 40 mg	>60 kg: 40 mg BID <60 kg: 30 mg BID Sustained release: >60 kg use 100 mg daily; <60 kg use 75 mg daily	Oral bioavailability: 86% Serum $t_{1/2}$: 1.0 hour Intracellular $t_{1/2}$: 3.5 hours Elimination: renal excretion ~50%	Can be administered without regard to meals
Non-Nucleoside Reverse Transcriptase Inhibitors[a]			
Rilpivirine (RPV) **Edurant** Preparations Tablets: 25 mg Complera: RPV 25 mg + TDF 300 mg + FTC 200 mg Odefsey: RPV 25 mg + TAF 25 mg + FTC 200 mg	25 mg daily Complera: one tablet daily	Oral bioavailability: not established Serum $t_{1/2}$: ~50 hours Intracellular $t_{1/2}$: unknown Elimination: hepatic metabolism primarily by CYP3A4 with 85% fecal excretion.	Take with moderate-to-high-calorie meal (increases absorption 40%)
Efavirenz (EFV) **Sustiva** Preparations Capsules: 50, 100, 200 mg Tablets: 600 mg	600 mg at bedtime Atripla one tablet at bedtime. Not for patients with CrCl <50 mL/minute	Oral bioavailability: ~60%–70% Serum $t_{1/2}$: 40–55 hours Intracellular $t_{1/2}$: unknown Elimination: hepatically metabolized by CYP2B6 and	Avoid taking with high-fat meals, concentrations ↑ 50% (increased risk for CNS toxicity)

Atripla: EFV 600 mg + TDF 300 mg + FTC 200 mg		CYP3A4 (also CYP3A4 mixed inhibitor/inducer)	
Etravirine (ETV) **Intelence** Preparations Tablets: 100, 200 mg	200 mg BID	Oral bioavailability: unknown Serum $t_{1/2}$: 40 ± 20 hours Intracellular $t_{1/2}$: unknown Elimination: hepatically metabolized by CYP3A4, CYP2C9, CYP2C19 (also 3A4 inducer, 2C9 and 2C19 inhibitors)	Take after a meal

Non-Preferred Non-Nucleoside Reverse Transcriptase Inhibitors[a]			
Nevirapine (NVP) **Viramune** Preparations Suspension: 50 mg/5 mL Tablets: 200 mg	200 mg PO daily × 14 days, then 200 mg PO BID	Oral bioavailability: >90% Serum $t_{1/2}$: 25–30 hours Intracellular $t_{1/2}$: unknown Elimination: metabolized by CYP2B6 and CYP3A4 (also a CYP3A4 inducer) with 80% excreted in urine as the glucuronide metabolite	Can be administered without regard to meals
Protease Inhibitors			
Darunavir (DRV) **Prezista** Preparations Tablet: 75, 150, 600, 800 mg Suspension: 100 mg/ml Prezcobix: DRV 800 mg + COBI 150 mg	DRV 800 mg + RTV 100 mg daily In patients with ≥1 DRV resistance mutations: DRV 600 mg + RTV 100 mg BID Prezcobix: one tablet daily	Oral bioavailability: 37% alone, 82% with RTV Serum $t_{1/2}$: 15 hours Intracellular $t_{1/2}$: unknown Elimination: hepatic metabolism via CYP3A4 (inhibitor)	Food ↑ C_{max} and AUC by 30%: administer with food
Atazanavir (ATV) **Reyataz** Preparations Capsules: 100, 150, 200, 300 mg Evotaz: ATV 300 mg + COBI 150 mg	400 mg daily Atazanavir/RTV: 300/100 daily Evotaz: one tablet daily	Oral bioavailability: 60%–70% Serum $t_{1/2}$: 6–7 hours Intracellular $t_{1/2}$: unknown Elimination: hepatic metabolism via CYP3A4 (modest inhibitor)	Take with food, and avoid acid suppressing agents (which prevent ATV solubility and absorption)
Lopinavir (LPV)/ritonavir (RTV) **Kaletra** Preparations Tablet: LPV 200 mg + RTV 50 mg Solution: LPV 80 mg+ RTV 20 mg per mL	Two tablets or 5 mL BID or Four tablets or 10 mL daily (recommended for treatment-naïve patients only)	Oral bioavailability: not determined Serum $t_{1/2}$: 5–6 hours Intracellular $t_{1/2}$: unknown Elimination: hepatic metabolism via CYP3A4 (inhibitor)	Take with food (increases AUC by 48%). Tablet stable at room temperature
Non-Preferred Protease Inhibitors			

Indinavir (IDV) **Crixivan** Preparations Capsule: 200, 333, 400 mg	800 mg every 8 hours (BID dosing ineffective when sole protease inhibitor) IDV/RTV: IDV 800 mg + 100 mg or 200 mg RTV BID	Oral bioavailability: 65% Serum $t_{1/2}$: 1.5–2 hours Intracellular $t_{1/2}$: unknown Elimination: hepatically metabolized via CYP3A4 (also inhibitor of CYP3A4)	Must be taken on empty stomach (1 hour before or 2 hours after a meal); may be taken with skim milk or low-fat meal Adequate hydration necessary (at least 1.5 L/24 hours of liquid) to minimize risk of nephrolithiasis
Nelfinavir (NFV) **Viracept** Preparations Powder for oral suspension: 50 mg per one level scoop (200 mg per one level teaspoon) Tablets: 250 and 625 mg	750 mg TID or 1,250 mg BID	Oral bioavailability: 20%–80% Serum $t_{1/2}$: 3.5–5 hours Intracellular $t_{1/2}$: unknown Elimination: hepatic metabolism via CYP3A4	Administer with meal or light snack (exposure increased twofold to threefold)
Saquinavir (SQV) **Invirase** (hard gel capsules) Preparations Hard gel capsule: 200 mg Tablets: 500 mg	Unboosted saquinavir not recommended Saquinavir/ritonavir: 1,000/100 BID; 1,600/100 daily under investigation	Oral bioavailability: 4% (as the sole PI) Serum $t_{1/2}$: 1–2 hours Intracellular $t_{1/2}$: unknown Elimination: hepatic metabolism via CYP3A4 (inhibitor)	Take within 2 hours of a meal and take with RTV
Fosamprenavir (FPV) **Lexiva** Tablet: 700 mg	In ARV-naïve patients: FPV 1,400 mg BID or FPV 1,400 mg + RTV 200 mg daily or FPV 700 mg + RTV 100 mg BID In PI-experienced patients: FPV 700 mg + RTV 100 mg BID	Oral bioavailability: not determined Serum $t_{1/2}$: 7.1–10.6 hours (APV) Intracellular $t_{1/2}$: unknown Elimination: hepatic metabolism via CYP3A4 (inhibitor)	Can be taken without regard to meals but should not be taken with high-fat meals

Tipranavir (TPV) **Aptivus** Capsules: 250 mg	TPV 500 mg + RTV 200 mg BID DO NOT USE WITHOUT RTV	Oral bioavailability: not determined Serum $t_{1/2}$: 6 hours Intracellular $t_{1/2}$: unknown Elimination: hepatic metabolism via CYP3A4 (inhibitor and inducer)	Administer with food to increase bioavailability
Entry Inhibitors			
Enfuvirtide (T-20) **Fuzeon**	90 mg SC BID in upper arm, thigh, or abdomen	Oral bioavailability: 84.3% compared with IV Serum $t_{1/2}$: 3.8 hours Intracellular $t_{1/2}$: not applicable Elimination: non-renal, non-	Reconstitute with 1.1 mL sterile water for injection; gently tap vial for 10 seconds and then roll

		hepatic	gently between hands to avoid foaming and ensure all drug is off vial walls After reconstitution, use immediately or refrigerate for 24 hours. Refrigerated T-20 should be brought to room temperature before injection
Chemokine Receptor Antagonists (CCR5)			
Maraviroc (MVC) **Selzentry** Preparations Tablet: 150, 300 mg	300 mg BID (with all NRTIs, NVP, TPV, ENF), 150 mg BID with CYP3A inhibitors (with or without a CYP3A inducer) including protease inhibitors (except tipranavir/ritonavir), delavirdine, ketoconazole, itraconazole, clarithromycin, and other strong CYP3A inhibitors (e.g., nefazodone, telithromycin) 600 mg BID with CYP3A inducers (without a strong CYP3A inhibitor) including Efavirenz, etravirine (TMC125), rifampin, carbamazepine, phenobarbital, and phenytoin	Oral bioavailability: ~33% Serum $t_{1/2}$: 14–18 hours Elimination: hepatic metabolism by CYP3A; 20% recovered in urine, 76% recovered in feces	Can be administered without regard to meals (high-fat meal decreases C_{max} and AUC by ~30%) Trofile assay must be performed before administration
Integrase Inhibitors			
Dolutegravir (DTG) **Tivicay** Preparations Tablet: 50 mg Triumeq: DTG 50 mg + ABC 600 mg + 3TC 300 mg	50 mg once daily 50 mg BID when coadministered with EFV, FPV/r, TPV/r, or Rifampin 50 mg BID when INSTI mutations present Triumeq: one tablet daily	Oral bioavailability: unknown Serum $t_{1/2}$: ~14 hours Intracellular $t_{1/2}$: unknown Elimination: hepatic metabolism by UGT1A1 (major) CYP3A4 (minor); 31% recovered in urine, 53% recovered in feces	Increased serum creatinine because of inhibition of tubular secretion not decreased renal glomerular filtration. Mean (range) increase from baseline = 0.15 (–0.32 to 0.65) mg/dL
Elvitegravir (EVG) **Vitekta** Preparations Tablet: 85, 150 mg Stribild: EVG 150 mg + COBI 150 mg + FTC 200	85 mg once daily if coadministered with ATV/r or LPV/r 150 mg once daily if coadministered with DRV/r 600/100 mg BID,	Oral bioavailability: not established Serum $t_{1/2}$: 9 hours when administered with RTV Intracellular $t_{1/2}$: unknown	Vitekta must be administered with ritonavir unboosted EVG is not recommended Take with food

mg + TDF 300 mg Genvoya: EVG 150 mg + COBI 150 mg + FTC 200 mg + TAF 10 mg	FPV/r 700/100 mg BID, or TPV/r 500/200 mg BID 50 mg BID when INSTI mutations present Stribild: one tablet daily	Elimination: hepatic metabolism by CYP3A, and UGT1A1/3; 6.7% recovered in urine, 94.8% recovered in feces	

Raltegravir (RAL) **Isentress** Preparations Tablet: 400 mg, 1,200 mg HD Chewable tablet: 25, 100 mg Single packet for oral suspension: 100 mg	400 mg BID or 1,200 mg (HD) daily	Oral bioavailability: not established Serum $t_{1/2}$: 9 hours Intracellular $t_{1/2}$: unknown Elimination: hepatic metabolism by UGT1A1 glucuronidation; 32% recovered in urine, 51% recovered in feces	Can be administered without regard to meals (high-fat meal decreases C_{max} by ~34% and increases AUC by ~19%)
Pharmacokinetic Enhancers			
Ritonavir (RTV) **Norvir** Preparations Oral solution: 80 mg/mL Capsules: 100 mg Tablets: 100 mg	RTV is a PI currently used as a pharmacokinetic enhancer for other PIs and EVG, using 100–400 mg/day in one to two divided doses	Oral bioavailability: Not determined Serum $t_{1/2}$: 3–5 hours Intracellular $t_{1/2}$: unknown Elimination: extensive hepatic metabolism via CYP3A4 (also potent CYP3A4 inhibitor and mixed inhibitor/inducer of other isozymes)	Take with food if possible to improve tolerability Dose should be titrated upward to minimize gastrointestinal adverse events Refrigerate capsules but not liquid or tablets Solution contains 43% alcohol
Tybost **(COBI)** **Cobicistat** Preparations Tablets: 150 mg Stribild: EVG 150 mg + COBI 150 mg + FTC 200 mg + TDF 300 mg Prezcobix: DRV 800 mg + COBI 150 mg Evotaz: ATV 300 mg + COBI 150 mg	150 mg daily when coadministered with ATV 300 mg daily 150 mg daily when coadministered with DRV 800 mg daily Stribild: one tablet daily. Not for patients with CrCl <70 mL/min Prezcobix: one tablet daily Evotaz: one tablet daily	Oral bioavailability: Not determined Serum $t_{1/2}$: 3–5 hours Intracellular $t_{1/2}$: unknown Elimination: extensive hepatic metabolism via CYP3A4 (also potent CYP3A4 inhibitor and mixed inhibitor/inducer of other isozymes) 8.2% recovered in urine, 86.2% recovered in feces	Not interchangeable with RTV Increased serum creatinine because of inhibition of tubular secretion not decreased renal glomerular filtration. Monitor for renal safety if increased from baseline >0.4 mg/dL

[a] In clinical trials, the NNRTIs were discontinued because of rash in 7% of patients taking nevirapine, 4.3% of patients taking delavirdine, and 1.7% of patients taking efavirenz. Rare cases of Stevens–Johnson syndrome have been reported with all three NNRTIs.

ABC, abacavir; ARV, antiretroviral; ATV, atazanavir; AUC, area under the curve; BID, twice daily; CNS, central nervous system; CrCl, creatinine clearance; COBI, cobicistat; ddI, didanosine; d4T, stavudine; DLV, delavirdine; DRV, darunavir; DTG, dolutegravir; EFV, efavirenz; ENF, enfuvirtide; ETV, etravirine; EVG, elvitegravir; FPV, fosamprenavir; FTC, emtricitabine; HLA, human leukocyte antigen; IDV, indinavir; IV, intravenous; LPV, lopinavir; MVC, maraviroc; NFV, nelfinavir; NNRTI, non-nucleoside reverse transcriptase inhibitor; NRTIs, nucleoside reverse transcriptase inhibitors; NVP, nevirapine; PI, protein inhibitor; PO, orally; QID, four times daily; RAL, raltegravir; RPV, rilpivirine; RTV, ritonavir; SC, subcutaneously; SQV, saquinavir; 3TC, lamivudine; TAF, tenofovir alafenamide; TDF, tenofovir disoproxil fumarate; TID, three times daily; TPV, tipranavir; TPV/r, tipranavir/ritonavir; T-20, enfuvirtide; ZDV, zidovudine.

DIAGNOSIS

CASE 76-1

QUESTION 1: E.J. is a 27-year-old man who presents with new complaints of fevers, night sweats, weight loss, and white patches in his mouth. He states that these symptoms have been present for the past 4 to 6 weeks. E.J. admits to intravenous drug use in the past; however, he states that he has been "clean" for 3 years. E.J. is diagnosed with thrush caused by Candida albicans. HIV infection is suspected and consent for an HIV test is obtained. Why is HIV suspected and how is it confirmed?

In otherwise healthy, immunocompetent individuals, opportunistic infections, such as thrush, are rare because an intact cell-mediated immunity protects against infection. In immunosuppressed individuals, such as those infected with HIV, the immune system is significantly compromised and places patients at risk for opportunistic infections. Infections such as shingles (herpes zoster), tuberculosis, thrush, and recurrent candidal vaginal infections in an otherwise healthy person warrant further evaluation for the possibility of HIV infection. More advanced diseases, such as P. jirovecii pneumonia, Mycobacterium avium bacteremia, and cytomegalovirus retinitis infections, among others, generally occur in patients with severely depressed immune systems and strongly suggest HIV infection. This suggestion is especially true for those patients with risk factors for HIV infection. Despite E.J.'s discontinuation of intravenous drugs, his prior use places him at

---

risk for HIV infection. Given his social history and current clinical presentation, an HIV test is warranted.

Laboratory methods used to diagnose HIV infection rely on detecting antigens produced by HIV viral replication or antibodies produced by the host's immune response to HIV infection. After HIV infection, there is an initial eclipse period where no antigen or antibody laboratory markers can be consistently detected.[55] The first laboratory marker that can be reliably detected in the plasma after infection is HIV RNA by nucleic acid tests (NAT) approximately 10 days after infection, then p24 (a protein produced during viral replication) approximately 4 to 10 days after HIV RNA can be detected. The immune response to HIV infection is characterized first by the production of anti-HIV immunoglobulin (Ig)M proteins (10–13 days after

HIV RNA can be detected) then IgG (18–38 days after HIV RNA can be detected). The period between infection with HIV and the ability to detect these antibodies is known as the seroconversion window, and the duration of this window can vary based on assay sensitivity or antibody type. Established infection is characterized by a fully developed IgG response.

While early laboratory methods which utilized enzyme-linked immunosorbent assays (ELISA) and confirmatory Western blot to detect anti-HIV IgG antibodies were highly sensitive (>99%), the turnaround time for test results could be up to 1 to 2 weeks and the seroconversion window was 1 to 2 months long, making it difficult to diagnose early infections.[55] Third-generation HIV assays decreased the seroconversion window by including anti-HIV IgM.[55] Fourth-generation antigen/antibody combination assays further reduced this timeframe by testing for p24 antigen and anti-HIV-1 and -2 IgM/IgG. Current Center for Disease Control (CDC) guidelines recommend using of one of two US Food and Drug Administration (FDA)-approved fourth-generation antigen/antibody combination assays.[56],[57] The sensitivity for these fourth-generation combination assays is >99.7%, and test results can be available within 3 hours which represents opportunity for more rapid engagement in clinical care upon a positive test result.[55] Unless there is reason to suspect very early infection, no further testing is required for a nonreactive antigen/antibody combination assay. Specimen with reactive antigen/antibody results should be further tested with an immunoassay to differentiate HIV-1 and HIV-2 antibodies. NATs for HIV RNA should be used to confirm an indeterminate antibody differentiation immunoassay or a negative antigen/antibody tests in patients where there is reason to suspect very early infection.[55]

SURROGATE MARKER DATA

While current guidelines recommend initiating therapeutic interventions for all HIV-infected persons ready to begin treatment,[3] the severity of immune damage and potential for disease progression should still be assessed to determine the clinical urgency for beginning treatment and if additional therapeutic interventions to prevent opportunistic infection are needed. As stated previously, HIV predominantly infects and destroys T cells. The larger the viral load, the greater the risk for T-cell destruction and opportunistic infections. Therefore, quantitative measurements of E.J.'s HIV viral load and T-cell counts will assist in "staging" the severity of infection, assessing the risk for disease progression, and providing a reference point (i.e., baseline) for future therapeutic decisions.

Identification and measurement of T-lymphocyte subsets (e.g., CD4, CD8) are based on flow cytometry readings of fluorescent-labeled monoclonal antibodies.[58] These values can vary widely on repeated laboratory evaluations, even in clinically stable patients. Patient samples can display up to 30% intralaboratory and interlaboratory variabilities.[3] Consequently, it is important to realize that assessment of T-cell measurements should always be interpreted as trends and not as individual values. Variability can also be minimized by using the same laboratory and by sampling patients at a consistent time of day.

The measurement of HIV viral load can be performed by one of three methods: reverse transcriptase–polymerase chain reaction (RT-PCR), branched-chain DNA assay, or nucleic acid sequence-based amplification.[59] Measurements using RT-PCR are obtained when viral RNA is amplified and counted. In contrast, branched-chain DNA amplifies and enumerates the signal from target probes attached to the viral RNA. Nucleic acid sequence-based amplification allows real-time, high throughput amplification of viral RNA. All methods report HIV RNA in plasma as the number of copies per milliliter but have differing lower limits of quantitation.[3] It should be recognized that plasma viral RNA values measure the amount of free virus in the periphery and not the lymph nodes. Because viral concentrations are substantially greater in the lymph node, plasma measurements of HIV indirectly reflect spillover from replication in that compartment.[60],[61]

Similar to CD4 counts, viral load measurements (copies/milliliter) can vary by as much as threefold (0.5 log) in either direction.[3] When obtaining a patient's baseline value, a number of issues must be considered. On initial infection with HIV, a burst of viremia occurs until the host's immune responses are able to control the infection. Consequently, viral load measurements obtained during the first 6 months of infection may not accurately reflect a true baseline value.[3] In addition, factors that activate the immune system, such as the development of a new opportunistic infection or immunizations,[62] can result in transient elevations of viral load measurements. In these situations, concentrations obtained within 4 weeks of the event may not accurately reflect the baseline viral load measurement.[3]

Some clinicians would recommend that at least two separate viral load measurements, which are obtained within 1 to 4 weeks of each other, be performed before making decisions regarding therapeutic options.[3] As with T-cell values, viral load measurements should be evaluated as trends.

In addition to quantifying the viral load, baseline resistance testing should be performed, using either genotypic or phenotypic testing,[3] to guide the selection of the initial regimen. Resistance testing is recommended in most clinical situations before beginning treatment, because the rate of transmission of virus resistant to at least one drug (i.e., transmitted drug resistance) has been noted in up to 11% to 12% of HIV-infected patients who have never been on antiretroviral therapy in North America and Europe.[63] (see Resistance, Viral Genotyping, Phenotyping, and Viral Fitness section for further discussion).

CASE 76-1, QUESTION 2: E.J.'s HIV-1/2 antigen/antibody combination immunoassay is reactive and the antibody differentiation immunoassay detects HIV-1 antibodies. He is informed of his HIV status the next week at his follow-up examination. Before making any decisions regarding therapeutic options, what additional laboratory tests should be obtained?

E.J. should have a baseline T-cell count, viral load measurement, and viral genotype obtained. A complete blood count, electrolyte panel, renal, and liver function tests and hepatitis B and C serology should be performed. If specific therapies are being considered, such as abacavir and maraviroc, specific testing is available to guide the appropriate use of these agents. HLA-B5701 screening is performed before starting a patient on abacavir because of an increased risk for exhibiting a hypersensitivity reaction in patients positive for this allele. Co-receptor tropism assay is performed before initiating maraviroc to determine whether the patient has a virus that predominantly uses CCR5 receptors (vs. ones that use primarily CXCR-4 receptors or ones that can use both).[3] These laboratory results help in selecting therapeutic options (see subsequent discussion) and establish baseline values in the event that problems are encountered in the future.

ANTIRETROVIRAL THERAPY

CASE 76-1, QUESTION 3: E.J.'s T-cell count and viral load measurement return at 225 cells/μL and 145,000 copies/mL (by RT-PCR assay), respectively. Should antiretroviral therapy be initiated?

In deciding to initiate antiretroviral therapy, it is important to consider both the potential benefits of therapy and the potential risks of therapy, including both short-term and long-term side effects and potential for the development of drug resistance (and cross-resistance; see subsequent discussion). Antiretroviral therapy should be offered to all patients who are willing and able to commit to lifelong treatment after an in-depth discussion of the benefits and risks of HAART and the importance of adherence. Recently, the Department of Health and Human Services (DHHS) HIV Treatment Guideline Panel issued a statement modifying their 2015 guidelines. This modification was based on the results of two large randomized clinical trials (START; The Strategic Timing of AntiRetroviral Treatment and the TEMPRANO ARNS 12136 Study). These trials investigated the risks and benefits of initiating HAART at a CD4 count >500 cell/μL versus delaying until the CD4 count declined to <350 cell/μL. A significant increase in morbidity and mortality was observed when HAART was delayed prompting the Guideline Panel to upgrade the strength of their former recommendation to start HAART at any baseline CD4 count to the highest level of evidence (AI; strong recommendation supported by data from randomized controlled trials).[64] Previously, the strength of evidence in support of initiating HAART was prioritized across three categories of increasing baseline CD4 cell count (>500 cell/μL: lowest strength; 350–500 cell/μL: intermediate strength;

<350 cell/μL: highest strength).[3] In further support of starting HAART regardless of baseline CD4 count, the 2015 guidelines recognize the benefits of initiating HAART for HIV prevention and support initiating HAART to prevent perinatal and heterosexual transmission (AI evidence rating) or other transmission risks (AIII evidence rating). Clinical situations which favor more urgent initiation of HAART include pregnancy; AIDS-defining condition such as an opportunistic infection; CD4 count of <200 cells/μL; HIV-associated nephropathy (HIVAN); hepatitis B and/or C coinfection; rapidly declining CD4 count (>100 cells/μL decrease per year); higher baseline viral load (>100,000 copies/mL); and acute/early HIV infection.[3] In patients who are asymptomatic, assessment of the patient's surrogate marker data (T-cell count, viral load measurements), concurrent medical conditions, medication adherence history (if any), and motivation to initiate therapy are necessary. The results of resistance testing should be considered before initiating therapy.

Knowledge of both the T-cell count and the baseline viral load values is important to "stage" the severity of infection (Table 76-1). In otherwise healthy, immunocompetent persons, T-cell measurements are greater than 1,200 cells/ μL. In patients who have been chronically infected with HIV, significant T-cell destruction occurs. When T-cell counts fall to less than 500 cells/ μL, patients are at increased risk for opportunistic infections. Data from both clinical trials and observational cohort studies have long shown a clear benefit for antiretroviral therapy when CD4 cell counts are ≤350 cells/μL, and many cohort analyses have shown benefit for starting therapy at CD4 counts ≤500 cells/μL.[3] Early, less definitive evidence also suggested initiating HAART in patients with CD4 counts of >500 cells/ μL improves immune recovery, reduces HIV transmission risk, and potentially reduces the risk of non–AIDS-defining diseases. These suggestive data were recently confirmed by the two previously mentioned randomized trials, START and Temprano ANRS 12136 study, both of which found definitive benefit when initiating HAART at a CD4 Count >500 cells/μL versus delaying.[65],[66] The risk of disease progression is closely tied to CD4 cell counts, with low CD4 counts (<200 cells/μL) predicting both short-term and long-term risk of disease progression.[67–69] High viral load (>100,000 copies/mL), increasing age, acquisition of infection through intravenous drug use, and a previous AIDS diagnosis also increase the risk of disease progression in observational cohorts.

The decision to initiate therapy should not be taken lightly. Antiretroviral regimens may improve the quality and duration of a patient's life, but they are not without risks. Once therapy is initiated, antiretroviral therapy is a lifetime commitment. For some patients, this may be a difficult realization, particularly if the patient is relatively healthy. In addition, the risk of adverse events/toxicities and the costs of HAART should be considered before beginning treatment. These guidelines, therefore, should be used to initiate discussions with the patient regarding the risks and benefits of therapy. It is critical for practitioners to talk openly with patients about their fears and concerns and make an assessment about their motivation to initiate therapy and ability to adhere to a lifelong regimen. The patient should always make the final decision after careful discussions with the practitioner.

E.J. has a number of significant risk factors for disease progression. He is clinically symptomatic with oral thrush and nonspecific constitutional symptoms (e.g., fevers, night sweats, and weight loss). His surrogate maker data place him at risk for greater disease progression (T-cell count <500 cells/µL and viral load >100,000 copies/mL). Based on these values, E.J. should be counseled on his risk of disease progression, potential adverse events associated with both starting and deferring treatment, and his willingness to adhere to a regimen.

Before developing a patient-specific regimen, it is important to recognize the benefits and limitations of therapy and identify obtainable and realistic goals.

CASE 76-1, QUESTION 4: After careful discussions, E.J. agrees to initiate therapy. What should be the goals of therapy? What other factors or information should be considered in selecting an appropriate regimen?

Goals of Therapy

GOAL 1: MAXIMALLY AND DURABLY SUPPRESS VIRAL LOAD

Maximal viral suppression often results in significant increases in T-cell counts and improved clinical outcomes. Based on our understanding of viral pathogenesis, this finding is not surprising. Lower amounts of replicating virus result in decreased risk for T-cell infection and destruction and, subsequently, a more intact immune response. Therefore, therapy should suppress viral replication to undetectable levels in the plasma (<50 copies/mL), for as long as possible.[3,5] The development of new antiretroviral agents with improved potency, higher genetic barrier to resistance, low adverse event profiles, and more convenient dosing regimens (including once daily single tablet regimens) makes viral suppression a reasonable goal in most patients, even those who previously have received multiple suboptimal regimens or failed therapy. In the treatment-experienced patient, however, special care must be given to designing a regimen that will suppress viral load, yet not contribute to the development of drug resistance that limits future treatment options. Consultation with an expert in antiretroviral resistance patterns is critical to designing a salvage regimen in such patients.

The development of drug resistance is also a consideration in the selection of regimens for patients who have not previously used antiretrovirals (antiretroviral naïve). In any given viral population, the potential exists for a spontaneous mutation to occur, which results in a resistant isolate. The larger the population, the greater the risk for mutations. HIV replication is a highly error-prone process, especially with the reverse transcriptase enzyme. Given the high rate of viral replication, the potential exists for the daily production of thousands of replication-competent viral mutations to each and every site on the HIV genome (~10,000 nucleotides in length).[4],[35] Under selective pressures from inadequate antiretroviral therapies, spontaneously produced isolates with reduced susceptibility to the given regimen eventually flourish and repopulate the host. This fact is of particular concern given the potential for cross-resistance between antiretroviral agents (see the following discussion of resistance). Therefore, the use of a regimen that fully suppresses viral replication reduces the potential for mutations and the development of cross-resistance.

Although more than 20 FDA-approved antiretroviral agents are currently available to use in combination therapies, many of these agents display similar resistance profiles. Developing resistance to one or more agents in a given regimen may result in the loss of activity to other agents with similar resistance profiles (i.e., cross-resistance).[4] Whether or not drug resistance develops is determined by the genetic barrier associated with the individual antiretroviral drugs. Some drugs have low genetic barriers; that is, only one or two critical changes in the virus are necessary for resistance to occur. An example of a class of agents with a low genetic barrier is the NNRTIs. While a number of individual point mutations in the viral genome can confer the loss of activity for the first-generation NNRTIs (nevirapine and efavirenz), second-generation NNRTIs (rilpivirine and etravirine) exhibit improved barriers to resistance compared to these first-generation agents. In contrast, the PIs have a wide genetic barrier, which requires multiple changes to the viral genome to incur resistance.[4]

It should be recognized, however, that just because an agent has a low genetic barrier does not mean it is virologically inferior or less potent. Potent regimens containing NNRTIs are highly effective and provide durable treatment responses. The potency of the entire regimen[3] is critical to determining whether or not drug resistance develops. If viral replication is suppressed, the development of resistance will be minimal. When viral replication does occur, the greater the replication, the greater the risk for development of resistance. In those situations in which viral replication does occur, inclusion of a drug with a low genetic barrier in the antiretroviral regimen may be risky and could result in the loss of activity of the drug, the development of cross-resistance to other drugs, or both. As a result, an antiretroviral regimen should be selected that has a high likelihood of suppressing viral replication and to which the patient will strictly adhere.

GOAL 2: PRESERVE AND STRENGTHEN THE IMMUNE SYSTEM

Decreasing viral replication usually leads to increased CD4 cell counts, which strengthens and preserves the immune system. With increased cell counts, patients are at lower risk for exhibiting opportunistic infections and death. With newer and improved regimens, strengthening and preserving the immune system may be possible even in treatment-experienced patients, although drug regimens must be designed carefully to prevent developing further resistance. Full immune reconstitution may not be possible if the CD4 cell count is low for a long period of time; however, it is reasonable to try and restore immune function as fully as possible. Despite advances in drug therapy, it is important to remember that HIV remains an incurable condition.

GOAL 3: LIMIT DRUG ADVERSE EVENTS, PROMOTE ADHERENCE, AND IMPROVE QUALITY OF LIFE

Treatment with combination therapy has been shown to be highly effective in suppressing HIV replication and improving survival among patients who are HIV infected. Lifelong adherence to an antiretroviral regimen is required and can be a complex and difficult task, although advances in coformulation of drug products and the advent of ritonavir-boosted protease inhibitors have simplified HIV treatment considerably. Several once-daily regimens and single tablet regimens are recommended as first-line therapy (Tables 76-3 and 76-4). The patient's ability to adhere to therapy may, however, still be the difference between a regimen that fails and one that results in a clinical benefit. The first regimen generally provides the best chance for treatment success. Although newer antiretrovirals tend to exhibit better adverse event profiles compared to the early antiretrovirals, adverse events can still make tolerating these regimens difficult, and affect drug adherence and response to therapy. Changes in body composition (known as lipodystrophy), increases in lipids and triglycerides, bone and joint fractures, increased risks for cardiac disease, and the development of lactic acidosis are serious concerns.[3]

Limit Adverse Events

Although new antiretrovirals offer marked improvement over early generation agents' toxicity profiles, lifelong HAART is not without risk. Metabolic complications from antiretroviral therapy include abnormal distribution of body fat, lipid abnormalities (e.g., hypercholesterolemia, hypertriglyceridemia, increases in low-density lipoprotein [LDL] and decreases in high-density lipoprotein [HDL]), and new-onset diabetes.[70–72] Coronary artery disease, myocardial infarctions, and vascular complications among relatively young patients (30–40 years old) taking HAART-containing regimens have been reported.[73–78] Large observational studies suggest an increased risk for cardiovascular disease among patients taking HAART, particularly among those receiving protease inhibitors.[79–81] Additionally, nucleoside analogs can inhibit mitochondrial DNA polymerase and, as a result, have been implicated in lipoatrophy; however, this appears to be less of a concern for newer NRTIs.[82] Finally, metabolic abnormalities have also been reported in patients who are HIV infected before receiving HAART, and it may also be a consequence of HIV infection or preexisting metabolic disorders that are exacerbated by HAART.[71]

Up to 40% of patients on PI-based HAART are reported to experience impaired glucose tolerance because of significant insulin resistance.[83] Patients with type 2 diabetes mellitus are at increased risk, and PI-based regimens should be used with caution in these patients. Fasting glucose measures for all patients are recommended before and during therapy (e.g., every 3–6 months) with PI-based regimens.[3] Treatment of type 2 diabetes in HIV patients as a result of HAART therapy should be handled similarly to any other patient.

Elevations in serum levels of triglycerides, total cholesterol, and LDL, with mild decreases in HDL, are associated with HAART.[71,84,85] These abnormalities may be seen as early as 2 weeks after the initiation of therapy.[71] Although all PIs have been implicated, these laboratory abnormalities appear to occur more frequently in ritonavir-containing regimens, and less frequently in patients receiving atazanavir alone.[71] The NNRTIs can also cause lipid alterations, although their incidence is lower. Both efavirenz and nevirapine have been shown to increase HDL concentrations among patients receiving HAART. Nevirapine may have the least detrimental lipid profile (i.e., greater increases in HDL concentrations and less effect on LDL elevations).[86] Of the NRTIs, stavudine appears to affect lipid profiles to the greatest extent: two prospective clinical trials have shown greater increases in triglycerides and total cholesterol among patients receiving stavudine-based HAART compared with zidovudine- or tenofovir-based regimens.[88–93] The management of HAART-associated hyperlipidemias should be handled similarly to hyperlipidemia in other patients with close attention paid to preventing drug–drug interactions.

Table 76-4

Recommended Antiretroviral Agents for Initial Treatment of Established Human Immunodeficiency Virus Infection

	Preferred[a]	**Alternatives**
PIs (one or two PIs + two NRTIs)	Darunavir/ritonavir + emtricitabine/tenofovir disoproxil fumarate or emtricitabine/tenofovir alafenamide	Darunavir/ritonavir + abacavir/lamivudine[b]
		Darunavir/cobicistat[c] + abacavir/lamivudine[b] or emtricitabine/tenofovir disoproxil fumarate or emtricitabine/tenofovir alafenamide
		Atazanavir/ritonavir + emtricitabine/tenofovir disoproxil fumarate or emtricitabine/tenofovir alafenamide
		Atazanavir/cobicistat[c] + emtricitabine/tenofovir disoproxil fumarate or emtricitabine/tenofovir alafenamide
Integrase inhibitors	Raltegravir twice daily + emtricitabine/tenofovir disoproxil fumarate	

	or emtricitabine/tenofovir alafenamide	
	Elvitegravir/cobicistat/emtricitabine/tenofovir disoproxil fumarate[c] or Elvitegravir/cobicistat/emtricitabine/tenofovir alafenamide	
	Dolutegravir + emtricitabine/tenofovir disoproxil fumarate or emtricitabine/tenofovir alafenamide	
	Dolutegravir/abacavir/lamivudine[b]	
NNRTIs (one NNRTI + two NRTIs)		Efavirenz/emtricitabine/tenofovir disoproxil fumarate
		Rilpivirine/emtricitabine/tenofovir disoproxil fumarate[d] or rilpivirine/emtricitabine/tenofovir alafenamide
Not recommended: Should not be offered	All monotherapies, dual-nucleoside regimens, triple-NRTI regimens	

[a] This table provides a guide to the use of available treatment regimens for individuals with no prior or limited experience on HIV therapy. In accordance with the established goals of HIV therapy, priority is given to regimens in which clinical trial data suggest the following: sustained suppression of HIV plasma RNA (particularly in patients with high baseline viral load), sustained increase in CD4+ T-cell count (in most cases >48 weeks), and favorable clinical outcome (i.e., delayed progression to AIDS and death). Additional consideration is given to the regimen's pill burden, dosing frequency, food requirements, convenience, toxicity, and drug interaction profile compared with other regimens. It is important to note that all antiretroviral agents have potentially serious toxic and adverse events associated with their use.

[b] Only for patients who are HLA-B*5701 negative.

[c] Only for patients with pretreatment estimated CrCl >70 mL/minute.

[d] Only for patients with pretreatment HIV RNA <100,000 copies/mL and CD4 count >200 cells/μL.

AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus; NRTI, nucleos(t)ide analog reverse transcriptase inhibitor; NNRTI, non-nucleos(t)ide analog reverse transcriptase inhibitor; PI, protease inhibitor.

Up to 40% to 50% of patients have been reported to experience alterations in body composition (fat loss [arms, legs, face, buttocks] and fat accumulation [dorsocervical fatty deposits or "buffalo humps"], increased abdominal girth), although the exact rate is confounded by differences in definition and assessment.[71] Risk factors for this complication include higher baseline body mass index, increased duration of exposure to antiretroviral agents, lower CD4 nadir at time of initiation of HAART, increasing age, female sex, and prolonged duration of HIV infection. The nucleoside analogs are likely responsible for lipoatrophy, whereas the PIs are believed to be responsible for lipoaccumulation,[71] although it is difficult to precisely identify which class of agents is responsible for which adverse event because they are given in combination.

The causes of lipodystrophy are unknown. It appears that there is greater propensity for lipoatrophy by those nucleoside analogs which greatly inhibit mitochondrial DNA polymerase in vitro (e.g., stavudine). Although substituting stavudine with an alternate NRTI such as zidovudine, tenofovir, or abacavir is associated with significant increases in arm and leg fat, and decreases in trunk fat (using radiographic tests such as dual-energy x-ray absorptiometry, computed tomography scans), these improvements are so modest that they may not be clinically relevant.[72],[89–93] The use of recombinant human growth hormone, an agent with lipolytic effects, decreases the size of buffalo humps and abdominal girth; however, the growth often returns once growth hormone therapy is stopped.[71] Tesamorelin, a growth hormone–releasing factor given as a 2-mg once daily subcutaneous injection, was approved in 2010. It is specifically indicated for the reduction of excess abdominal fat in HIV-infected patients with lipodystrophy.[94] Surgical excision or liposuction may be effective; however, recurrences, along with adverse events (intestinal perforation, intraperitoneal bleeding), have been reported.[95] For facial wasting, injection of fat or synthetic polymers into the recessed areas of the cheeks has shown good results, but it requires frequent costly administration and lacks long-term safety data.[96]

Other important long-term complications include nucleoside-associated lactic acidosis, osteonecrosis, and osteopenia.[71] Lactic acidosis has been predominantly associated with the use of older NRTIs (stavudine, zidovudine, and didanosine) which are no longer preferred antiretrovirals but has been reported with other nucleoside analogs. This complication is managed by discontinuing therapy until lactate levels return to normal and then reinitiating therapy with a non-stavudine or non-nucleoside analog-containing HAART regimen.[3] Tenofovir alafenamide (TAF), a novel formulation of tenofovir, is associated with improved long-term bone and renal outcomes compared to tenofovir disoproxil fumarate (TDF) in patients initiating therapy. [Ref 97: Wang H et al. The efficacy and safety of tenofovir alafenamide versus tenofovir disoproxil fumarate in antiretroviral regimens for HIV-1 therapy Meta-analysis. Medicine. 2016; 95:41(e5146).] With the availability of generic tenofovir disoproxil fumarate (FDA approved in June 2017), balancing lower cost vs improved safety will be an important consideration for clinicians in selecting a tenofovir based regimen.

Promote Adherence

While the exact degree of adherence required for clinical success is currently unknown and varies by antiretroviral class, taking 90% to 95% of prescribed doses is generally believed to be necessary to prevent the development of resistance. Data from studies evaluating adherence among HIV-infected patients indicates that approximately 62% of patients take ≥90% of the prescribed doses of antiretrovirals.[98] Although it is important to note that adherence patterns vary widely based on patient-specific factors. The four most common reasons for skipping antiretroviral doses are simple forgetfulness, a change in daily routine, being too busy with other things, and being away from home.[99] Factors associated with poor adherence include (a) the number of medications (the greater the number, the greater the likelihood of poor adherence); (b) the complexity of the regimen (special meal requirements, escalating or de-escalating doses, dose frequency); (c) special storage requirements; (d) interference of medication with lifestyle and daily activities; and (e) poor communication with primary care providers and other health care professionals. Comorbid psychiatric conditions, as well as substance abuse issues, are also significant barriers to adherence in the HIV-infected population. Incorporating these factors into the selection of a patient-specific regimen may improve adherence and, subsequently, the chance for an improved clinical outcome and quality of life.

To better address the complex, multidimensional, patient-specific structures that can influence adherence behavior and retention in care, the DHHS HIV Treatment Guidelines recommend that clinics adopt a multidisciplinary team approach which provides access to trustworthy case managers, pharmacists, social workers, nurses, psychiatric care providers, etc.[3] Additionally, before selecting an HIV treatment regimen clinicians should provide adherence-related education (including information regarding why adherence is important) and involve the patient in the antiretroviral selection process. Selecting a treatment plan that the patient can (1) understand and (2) commit to for the long term is critical for fostering lifelong adherence. Thus, considering the patient's daily schedule and their ability to comply with antiretroviral specific requirements (i.e., food requirements, drug interactions, etc.) is important. For example, rilpivirine should be consumed with a full meal (ideally ≥500 kcal) and therefore may not be the best option for a patient who frequently skips meals or does not have a consistent eating schedule. Efavirenz which may cause drowsiness and is generally taken before bed on an empty stomach to mitigate this CNS effect might not be the best option for a person who works night shifts where they are on for 7 days then off for 7 days. Involving patients in the selection of their antiretroviral regimen maximizes the possibility of selecting a regimen which is least burdensome to their daily routine and helps to reduce certain barriers which lead to poor adherence. After the antiretroviral regimen has been selected and treatment initiated, quickly identifying patients who are struggling with adherence (via patient self-report, pharmacy records, pill counts, etc.); identifying their specific barriers to adherence (i.e., pill fatigue, high co-pays, forgetfulness, etc.); and employing targeted interventions to improve adherence are essential. Examples of specific strategies to improve adherence can be found in Table 13 (**https://aidsinfo.nih.gov/contentfiles/lvguidelines/AA_Tables.pdf**) of the 2015 DHHS HIV treatment guidelines.[3]

GOAL 4: PREVENT HUMAN IMMUNODEFICIENCY VIRUS–RELATED MORBIDITY AND MORTALITY

By successfully treating HIV (suppressing viral load and restoring immune function), patients are at decreased risk for acquiring HIV-associated opportunistic infections. By achieving goals 1 through 3, goal 4 naturally follows, and truly this is the ultimate goal of the pharmacotherapy of HIV infection. With modern-day HAART therapy, patients infected with HIV are dying more frequently from non–HIV-related conditions common in the general population (i.e., cardiovascular disease, hepatic disease, non–HIV-associated malignancies).[100] Although this represents a significant achievement in care, it also provides increased complexity in caring for those who are both at risk for HIV-related illness and also receiving treatment for comorbid conditions. This increases the potential for drug–drug and drug–disease interactions.

The selection of a patient-specific regimen can be a complex decision. Many potential combinations can be used, but a number of general principles should be followed.[3],[5]

General Rules of Therapy

Initiation of therapy should occur soon after diagnosis in most patients.[3],[5] Many of the current regimens reduce viral replication to less than detectable levels, and result in durable treatment responses. Reasons for the current improved response rates include the simplification of the regimens (e.g., fewer pills per day, less frequent dosing per day, use of fixed-dose combination products), improvement in overall potency of the regimens, and minimization of short-term side effects. Consequently, if the correct patient-specific HAART regimen is selected as initial therapy, the patient should be able to adhere to therapy and gain both virologic and clinical benefits from the regimen.

CASE 76-1, QUESTION 5: On questioning, E.J. admits to having an occasional drink with dinner, but he is not currently using any illicit drugs and has not in 3 years. E.J. has no known drug allergies and is currently taking only omeprazole to help with stomach acid. He is employed as a construction worker and is extremely busy during the day, so he prefers to take medications only one time daily. His complete blood count, electrolyte, and liver and renal panel all return within normal limits. His baseline genotype does not indicate any transmitted drug resistance, and he is HLA-B*5701 negative. E.J. has no particular preference for a specific regimen and appears highly motivated to take control of his disease. What factors should be considered when selecting an appropriate antiretroviral regimen?

Select the type of antiretroviral regimen. In general, PI-based or INSTI-based combination HAART are preferred (Table 76-5). Currently, no evidence definitively recommends one regimen over another, and the selection is dependent on patient-specific factors, such as comorbid disease states, concomitant medications, and pill burden.

Avoid regimens that are not virologically additive or synergistic. Lamivudine and emtricitabine should not be used together because they have similar resistance profiles, and concomitant use will not confer any additional virologic benefit.

If PI-based HAART is desired, regimens combined with a pharmacoenhancer are preferred. Ritonavir, a potent inhibitor of cytochrome P-450 metabolism and P-glycoprotein (PGP) activity, interacts significantly with a number of agents, including other PIs. This inhibition can be exploited to decrease the metabolism

---

or increase the absorption of the other PIs. In some cases, such as in the use of lopinavir, tipranavir, and darunavir, the use of coadministered ritonavir is required for virologically relevant concentrations. The result is a regimen with more potent viral suppression. In addition, boosting allows for less frequent dosing, often lowers the total daily pill burden, and removes the need for drug/food restrictions. The pharmacoenhancer, cobicistat, can also be combined with atazanavir or darunavir (as well as the INSTI, elvitegravir) to provide a similar boosting effect as ritonavir without providing any antiviral effect. Because ritonavir and cobicistat are potent inhibitors of CYP3A4, they interact with a number of medications. Concomitant medications may require dosage adjustments, depending on the severity of the interaction.[3],[5]

Avoid regimens shown to be detrimental in specific patient populations. Examples include the use of efavirenz in women of childbearing potential who are not using reliable methods of birth control or who are in the first 8 weeks of pregnancy. Efavirenz is pregnancy category D because of an association with teratogenic effects in animals. Nevirapine has the potential for hepatotoxicity in patients with higher baseline CD4 cell counts (>250 cells/µL for women, >400 cells/µL for men).

CASE 76-1, QUESTION 6: What initial antiretroviral regimen should E.J. receive?

When selecting a patient-specific regimen, the following steps should be followed.

STEP 1: DETERMINE WHICH ANTIRETROVIRAL CLASS WILL BE USED

A careful review of the advantages and disadvantages of each regimen should occur (Table 76-5). For example, protease inhibitors may be less favored with a current medical condition consisting of coronary artery disease, hyperlipidemia, or diabetes mellitus because of their potential metabolic side effects.[3],[71]

After discussions with E.J., it appears that he is highly motivated to take control of his disease and is willing to initiate therapy. Subsequently, the use of a combination regimen with either a PI-based or INSTI-based regimen is appropriate. Potential initial treatment options are listed in Table 76-4.

STEP 2: OPTIMIZE AGENTS IN THE REGIMEN

The next step requires the selection of agents for the regimen. In many situations, absolute contraindications and significant drug–drug interactions limit the agents available for use in the regimen. The nucleoside or nucleotide reverse transcriptase inhibitors, including lamivudine, tenofovir disoproxil fumarate or tenofovir alafenamide, emtricitabine, and abacavir, are all potential options for E.J. With respect to drug interactions, a PI or INSTI can be administered safely with omeprazole.

STEP 3: QUALITY-OF-LIFE CONSIDERATIONS

When selecting a regimen, assessment of quality-of-life issues, potential adverse drug events, and patient preference should receive as much consideration as drug–drug interactions and absolute contraindications. In some situations, these issues could mean the difference between a regimen that is effective and one that is not. Considering E.J.'s lifestyle and work requirements, it is best to select a regimen that will minimally interfere with his daily activities. The selection of a regimen with once-daily or twice-daily dosing is appropriate (Table 76-3), although once-daily dosing might be preferred. Potential regimens include the PI-based regimen, darunavir boosted with ritonavir plus emtricitabine/tenofovir disoproxil fumarate or emtricitabine/tenofovir alafenamide all once daily, or an INSTI-based regimen such as raltegravir twice daily with emtricitabine/tenofovir disoproxil fumarate or emtricitabine/tenofovir alafenamide once daily, elvitegravir/cobicistat/emtricitabine/tenofovir or elvitegravir/cobicistat/emtricitabine/tenofovir alafenamide as a combination tablet once daily, dolutegravir plus emtricitabine/tenofovir disoproxil fumarate or emtricitabine/tenofovir alafenamide all once daily, or dolutegravir/abacavir/lamivudine as a combination tablet once daily.

Table 76-5

Advantages and Disadvantages of Antiretroviral Components for Initial Antiretroviral Therapy

ARV[a] Class	Possible Advantages	Possible Disadvantages
Dual NRTI	■ Established backbone of combination antiretroviral therapy ■ Less fat maldistribution and dyslipidemia than PI-based regimens	■ Rare but serious cases of lactic acidosis with hepatic steatosis reported (d4T > ddI = ZDV > TDF or TAF = ABC = 3TC = FTC) ■ Low genetic barrier to resistance (single mutation confers resistance)
NNRTI	■ Long half-lives ■ Single tablet regimens available with EFV and RPV	■ Low genetic barrier to resistance ■ Cross resistance among first-generation NNRTIs ■ Skin rash ■ Potential for cytochrome P-450 drug interactions ■ Transmitted resistance to NNRTIs more

		common than with PIs and INSTIs
PI	■ Higher genetic barrier to resistance ■ PI resistance uncommon with failure (boosted PIs) ■ More forgiving to intermittent adherence	■ Metabolic complications (fat maldistribution, dyslipidemia, insulin resistance) ■ Cytochrome P-450 substrates, inhibitors, and inducers (potential for drug interactions)
INSTI	■ Well tolerated ■ Single tablet regimens available with EVG and DTG ■ Fewer drug–drug interactions with RAL and DTG than PI- or NNRTI-based regimens ■ Achieve rapid viral load suppression	■ Less long-term experience than with boosted PI-based regimens ■ Lower genetic barrier to resistance than boosted PI-based regimens

[a] Adapted from DHHS treatment guidelines July 2016. See full guidelines for discussion of the advantages and disadvantages of each individual ARV agent.

ABC, abacavir; ARV, antiretroviral; DHHS, Department of Health and Human Services; DTG, dolutegravir; EVG, elvitegravir; FTC, emtricitabine; NNRTI, non-nucleoside reverse transcriptase inhibitors; NRTI, nucleoside reverse transcriptase inhibitor; PI, protease inhibitor; INSTI, integrase strand transfer inhibitor; RAL, raltegravir; TAF, tenofovir alafenamide; TDF, tenofovir disoproxil fumarate; 3TC, lamivudine.

CASE 76-1, QUESTION 7: E.J. is starting emtricitabine, tenofovir, disoproxil fumarate, elvitegravir, and cobicistat (coformulated for once-daily dosing as Stribild). How should therapy be monitored? Are any additional laboratory tests necessary? What adherence support should be provided?

Short-Term Assessments

Three important criteria determine whether an antiretroviral regimen is effective: clinical assessment, surrogate marker responses, and regimen tolerability, including a patient's ability to adhere to the regimen.[3,5] In patients who are clinically symptomatic (e.g., constitutional symptoms such as fatigue, night sweats, and weight loss; new opportunistic infections), the initiation of an appropriate antiretroviral regimen often results in resolution of symptoms, increased strength and energy, and improvement in overall well-being. In some patients, however, the effect may not be as prominent. A careful assessment of clinical symptoms should therefore be regularly performed at all follow-up appointments.

In all patients, repeat viral load and T-cell measurements are necessary. This early value allows clinicians to assess the magnitude of response and ensures declining viral load measurements. Therapy with an effective regimen will result in at least a threefold (0.5 log) and tenfold decrease (1.0 log) in viral load counts by weeks 4 and 8, respectively.[3,5] The viral load should continue to decline during the next 12 to 16 weeks and, in most patients, it will become undetectable.[3,5] Long-term response to therapy correlates with the magnitude of viral suppression on initiation of a regimen.

The greater the suppression, the greater the durability of response to that regimen.[101] The speed and magnitude of suppression, however, can be affected by a number of factors, including clinical status of the patient (e.g., more advanced disease–low T-cell counts, high viral load value), adherence to therapy, and overall potency of the regimen.[3,5]

In response to declining viral replication, T-cell destruction slows, and eventually cellular repopulation occurs. The magnitude of this T-cell increase can vary significantly, with some patients experiencing large increases (≥500 cells/μL) and others experiencing little or no change. Given that T-cell changes do not occur rapidly, once therapy is initiated, repeat T-cell counts should be obtained at 3-month to 4-month intervals.[3,5]

A seemingly worsening of symptoms may also occur after the initiation of potent antiretroviral therapies because of immune reconstitution.[102–104] In patients with advanced HIV disease (i.e., CD4 <100 cells/μL), significant immune dysfunction results in an inability to mount an appropriate response to subclinical infections. As a result, these infections replicate unimpeded and often undetected by the host (also known as quiescent disease). During the first 12 weeks of therapy, an increased immune response results from redistribution of memory cells,[105–107] and inflammation occurs at the site of infection. The immune reconstitution inflammatory syndrome can present in any organ system where quiescent disease exists (e.g., CNS, eyes, lymph nodes). Most cases occur within 1 to 4 weeks after the initiation of potent antiretroviral therapies.[3]

A patient's tolerability of the regimen, which includes involvement in the decision of what therapy to initiate, ease of administration, and avoidance of intolerable side effects, is vital to a patient's willingness and ability to adhere to an antiretroviral regimen. If the patient is not adherent, they are at risk for clinical failure and the development of resistance. Adherence should be evaluated at every clinic visit and the type and reason for identified non-adherence should be assessed. If adherence is not a present concern, then positive reinforcement and encouragement are recommended.[3]

CASE 76-1, QUESTION 8: After initiation of therapy, E.J.'s viral load values are 7,000 copies/mL at 4 weeks and less than 50 copies/mL (undetectable) at 14 weeks. His T-cell counts have increased from 225 to 525 cells/μL. In addition, E.J. states that his night sweats and fevers have disappeared, he "feels great," and that he has had no drug-related problems. Is the therapy effective? How should therapy be monitored?

E.J.'s response to elvitegravir/cobicistat/emtricitabine/tenofovir disoproxil fumarate does indicate efficacy. Clinically, his symptoms have subsided and his overall health is much improved. His viral load measurements have responded appropriately and are now less than the level of assay detection. T-cell counts have increased by 300 cells/μL. Finally, E.J. has experienced no drug-related adverse events. Given the response to date, no changes are required and the current regimen should be continued.

Long-Term Assessments

Once the prescribed regimen has been stabilized, the long-term goals are to maintain maximal viral suppression, sustain clinical and immunologic improvements, and maintain drug tolerability. Periodic assessments should be made of viral load and T-cell counts (every 3–6 months).[3],[5] These surrogate marker data allow clinicians to monitor trends in viral activity and immunologic status and assist them in identifying early regimen failure. Clinical assessment of the patient questioning of tolerability and adherence to the prescribed regimen should occur at the 3- to 6-month follow-up visits.

Treatment Failure

CASE 76-1, QUESTION 9: E.J. has remained on elvitegravir/cobicistat/emtricitabine/tenofovir disoproxil fumarate for more than a year. To date, his T-cell counts have remained stable at 550 cells/ µL, and his viral load measurements have remained less than the limit of assay detection. He presents with new complaints of fevers and malaise. E.J. reports that he has been compliant with therapy and has not started any new medications. Repeat laboratory tests now show E.J.’s viral load is 3,000 copies/mL and his T-cell count is 375 cells/µL (both repeated and validated). Should E.J.’s regimen be changed?

Assessment of regimen failure should be based on (a) clinical symptoms, (b) surrogate marker data, and (c) regimen tolerability and adherence.[3–5]

In some patients, the first sign of failure is a change in signs and symptoms. These changes can be subtle (e.g., increase in constitutional symptoms, new onset of oral thrush) or more severe (e.g., new opportunistic infections) and suggest a failing regimen and need to change therapy.

Assessment of efficacy should also involve evaluation of surrogate marker data (e.g., T cells and viral load). In many situations, changes to these markers occur before any noticeable clinical signs and symptoms. Therefore, careful evaluation of surrogate marker data may allow for intervention before any significant immune destruction occurs. Virologic failure, defined as new or continued viral replication despite appropriate antiretroviral therapy, suggests a failing regimen. For example, patients with repeated detection of virus in plasma after initial suppression to undetectable levels should be evaluated as potential treatment failures. In patients who do not achieve viral suppression to less than detectable levels, a significant increase in viral replication should also be viewed as a treatment failure.[3],[4]

When assessing viral load, it is important to recognize that these values can increase from vaccinations or other concurrent infections (see Case 76-1, Question 2). Therefore, a thorough medical history should be taken to rule out other causes of increasing viral load. In addition, laboratory values should be interpreted as trends over time and not necessarily as individual measurements. A repeat viral load should be performed and evaluated within 4 weeks of the initial viral load increase. In some cases, transient viral “blips” occur (increases in viral load measurements just above the level of assay detection (e.g., 50–1,000 copies/mL), which become undetectable at the next visit.[107],[108] The clinical significance of viral blips is unknown and, although they may not directly reflect treatment failure, they may represent near future viral breakthrough because of either patient non-adherence or insufficient antiretroviral potency.[109],[110] Careful follow-up of these patients is required, because changes to the current HAART regimen may be necessary.

Table 76-6

Metabolism and Drug–Drug Interaction Potential of Antiretroviral Classes

Class	General Metabolism and Drug–Drug Interaction Considerations	Exceptions
NRTIs	Renally eliminated, few drug–drug interactions	ABC is metabolized by alcohol dehydrogenase and competes with alcohol for metabolism
NNRTIs	CYP3A4 substrates CYP3A4 inducers	RPV is a CYP3A4 substrate only ETR also a CYP2C9, CYP2C19 substrate/inhibitor
PIs	CYP3A4 & PGP substrates CYP3A4 inhibitors	RTV is also a CYP2D6 substrate/inhibitor ATV also inhibits UGT1A1 TPV is also a CYP2D6 inhibitor and PGP inducer
INSTI	UGT1A1	EVG is a CYP3A4 substrate, given with COBI a potent CYP3A4 inhibitor DTG is also a UGT1A3 and PGP substrate
CCR5	CYP3A4 substrate	

ABC, abacavir; CCR5, chemokine co-receptor 5; COBI, cobicistat; DTG, dolutegravir; EVG, elvitegravir; ETR, etravirine; INSTI, integrase strand transfer inhibitor; NRTI, nucleos(t)ide reverse transcriptase inhibitor; NNRTI, non-nucleoside reverse transcriptase inhibitor; PI, protease inhibitor; PGP, P-glycoprotein; RPV, rilpivirine; RTV, ritonavir; TPV, tipranavir.

In response to increasing viral replication, T-cell destruction occurs. Persistently declining T-cell counts, with or without increasing viral load measurements, represent treatment failure and suggest a change in therapy is warranted.

Other potential causes for failure include non-adherence and drug–drug interactions. In the event of non-adherence, discussions regarding tolerability, number of doses missed, duration of non-adherence, and lifestyle changes should take place. The decision to reinitiate a prescribed regimen should take into account the future likelihood of adherence and the potential development of resistant strains. In those patients with a history of long-standing non-adherence, the success of reinitiating the prescribed regimen may be limited. Stopping all antiretrovirals at once poses less risk for the development of resistance than intermittent adherence to some or all of a regimen. The precise effect of the duration and extent of nonadherence on the development of resistance cannot be fully anticipated and is dependent on the barrier to resistance of the patient's ART. For the virus to mutate, sufficient drug pressure must be placed on the virus.

Significant drug interactions could also contribute to reduction in oral bioavailability or increased metabolism of the HIV medications leading to low serum concentrations, resulting in failure.[3] In addition, many medications require certain food requirements to allow maximal drug absorption. A careful review of all new medications and their potential for clinically significant drug interactions should be evaluated at all visits (Table 76-6).

Currently, E.J. has a number of signs and symptoms that suggest a failing regimen. E.J. is experiencing new symptoms of fevers and malaise not attributable to any other cause. E.J.'s viral load value has become detectable at 3,000 copies/mL without evidence of concurrent infections or vaccinations in the past 4 weeks. E.J.'s T-cell counts have declined from 550 to 375 cells/μL. Finally, it appears that E.J. has been adhering to his therapy and has not started any new medications that could affect the efficacy of his current regimen. Therefore, a change in therapy is necessary.

CASE 76-1, QUESTION 10: What potential antiretroviral regimen(s) can be considered for E.J.?

In addition to the general rules of therapy described in Case 76-1, Question 5, other issues should be considered when selecting an alternative regimen for a patient failing therapy.[3],[4]

GENERAL RULES FOR CHANGING THERAPIES

1. If possible, the new regimen should contain at least two, preferably three fully active agents. The potential for cross-resistance between antiretroviral drugs should be considered when choosing new regimens, and therefore resistance testing should provide useful information (see Case 76-2, Question 2).
2. Given that antiretroviral drug resistance is more likely to occur with increased and prolonged viral replication in the presence of antiretroviral agents, changes to therapy should occur close to the time of treatment failure. Prolonged treatment with a failing regimen is likely to result in the accumulation of resistance mutations (particularly with protease inhibitors), which may limit future treatment options.
3. Resistance testing is recommended to guide the selection of future drug regimens. Optimally, testing via genotype, phenotype, or virtual phenotype should occur while the patient is taking the failing regimen, or within 4 weeks of discontinuation to increase the likelihood of detecting resistant isolates. These tests cannot reliably detect mutations at viral concentrations less than 1,000 copies/mL and may have limited usefulness in patients with persistent low-level viremia.
4. To prevent the development of resistance, one new drug should never be added to failing regimen. An exception to this rule is if the initial response to a first regimen has been inadequate (e.g., undetectable viral load at 16–20 weeks). In this

situation, some clinicians may intensify therapy with an additional agent provided that the viral load measurements were trending downward since initiation of therapy.

5. If possible, a regimen that has failed in the past should not be reinitiated, because an isolate resistant to the failed regimen could continue to reside within various compartments of the

---

body. If a regimen to which the patient had previously failed were restarted, unimpeded viral replication of the resistant strain would occur, repopulate the host, and eventually result in treatment failure. In some situations (e.g., patients with advanced disease, limited treatment options, and prior exposure to most antiretroviral agents), it may be necessary to reinitiate agents or regimens in combination with additional new agents with the goal of suppressing viral replication.

6. When treatment failure is a direct result of drug toxicity (rather than poor drug efficacy), the offending agent should be replaced with an alternative drug from a similar class, provided that the potential for cross-resistance is minimal.
7. If an agent in a given regimen must be stopped, it is recommended that all agents in the regimen be stopped and restarted simultaneously to prevent the development of resistance. An exception to this rule is when components of a regimen have differing half-lives, such as NNRTIs and NRTIs. In this situation, if all drugs are discontinued simultaneously, continued monotherapy exposure with the NNRTI is likely to result, because of the much longer NNRTI half-life. Consequently, some experts recommend continuing the NRTIs for 1 to 2 weeks past NNRTI discontinuation to provide combination therapy while the NNRTI is eliminated from the body (covering the “tail” of the pharmacokinetic profile).

It should be recognized that many alternative regimens are based on theoretical benefits or limited data. In addition, many potential options could be limited in some patients based on prior antiretroviral use, toxicity, or past intolerances. Therefore, the clinician should carefully discuss these issues with the patient before changing therapy.

Because E.J. is failing to respond to his current regimen, a new antiretroviral regimen must be chosen. In addition to selecting susceptible agents from resistance testing, the new regimen should take into consideration quality-of-life issues. In E.J.’s situation, it is reasonable to switch to a ritonavir-boosted PI regimen, with two or more nucleoside agents as dictated by the viral resistance profile.

Considerations in Antiretroviral-Experienced Patients

CASE 76-2

QUESTION 1: H.G. is a 56-year-old, HIV-positive man with an extensive history of treatment with a variety of antiretroviral agents. He took zidovudine monotherapy in the late 1980s and early 1990s. When lamivudine became available, he took the combination of zidovudine and lamivudine until he failed therapy about 20 years ago. At that time, he began experiencing zidovudine-induced myopathies. Since that time, H.G. has been "on and off" various regimens without sustained clinical benefit. He is currently taking emtricitabine/tenofovir disoproxil fumarate and atazanavir/ritonavir with a CD4 count and viral load measurement of 55 cells/μL and 48,000 copies/mL, respectively. These laboratory values have been stable for the last 9 months. How do patients with extensive antiretroviral histories differ from antiretroviral-naïve patients? Are there any special considerations when selecting therapeutic regimens for patients such as H.G.?

Patients who have been infected for 20 or more years may have been treated with many different regimens, both experimental and FDA approved. As a result, many potential regimens have already been exhausted; thus, there are fewer viable choices left. Agents with higher barriers to resistance that do not have cross resistance with older agents and agents with novel mechanisms of action are useful in these patients. Although, now a preferred agent in treatment naïve patients, darunavir was specifically marketed for highly treatment-experienced patients because of its high genetic barrier to resistance and limited cross resistance with other PIs.[3],[4] The second-generation NNRTIs, etravirine and rilpivirine, have minimal cross resistance with the first-generation NNRTIs, efavirenz and nevirapine.[3],[4] Maraviroc, the first CCR5 receptor antagonist approved by the FDA, is also an option for treatment-experienced patients infected with HIV-1 utilizing this co-receptor and failing current treatment. Maraviroc is not recommended for use in patients with dual-trophic viral populations (i.e., able to use CXCR-4 or CCR5 as co-receptors) or CXCR-4-trophic virus and, thus, patients with extensive treatment histories should undergo tropism testing before maraviroc is initiated. Additionally, INSTIs are newer agents with a novel mechanism of action that allow for use in patients with extensive reverse transcriptase or protease mutations. Some highly treatment-experienced individuals will have extensive resistance patterns that limit their therapeutic options. In such patients, full suppression of viral load and immune reconstitution may not be possible.[3],[4]

Patients who have experienced several antiretroviral regimens present other unique challenges for clinicians and require consideration of the following factors.

1. Regimen tolerability: Patients with advanced HIV disease display decreased tolerability to many medications, including antiretroviral agents. Although this is not fully understood, it is probably a result of HIV-induced immune alterations and cytokine dysregulations. Subsequently, clinicians evaluating patients with advanced disease should be alert for possible drug-induced adverse events.
2. Drug interactions: Many patients with advanced disease take numerous medications for primary or secondary prophylaxis of various opportunistic infections, as well as other medications for comorbid disease states. Subsequently, the risk for a drug–drug interaction is increased. The addition of any new medication, either prescription or over-the-counter, should be carefully evaluated for potential

interactions with the patient's current antiretroviral regimen (see Table 76-6). In addition, any change to the current antiretroviral regimen should also be checked against the patient's current medication list.

3. Altered bioavailability: Patients with advanced HIV infection may have unreliable absorption of many medications because of severe diarrhea, anorexia, weight loss, wasting, and gastric achlorhydria. As a result, the bioavailability of some agents, especially certain PIs that require specific dietary requirements, may be affected (Table 76-3). Any changes in dietary habits or bowel function should be carefully assessed in light of the potential impact on the antiretroviral regimen.
4. Antiretroviral drug histories and resistance testing: The most useful information to guide the choice of alternative regimens is a detailed drug history, in conjunction with appropriate resistance testing. Among patients with extensive prior antiretroviral use, it is critical to identify previously failed regimens and determine the precise cause of the failures. In an experienced patient who has taken many different regimens over a lifetime, the number of remaining viable agents and regimens may be limited. Therefore, it is important to determine whether prior regimens truly failed for virologic reasons or some other cause (e.g., regimen intolerability or an inadequate trial period). In addition, detailed knowledge of regimen intolerabilities and which agent(s) caused the adverse event will help in the selection of a new appropriate regimen. In some situations, the offending agent may be reinitiated if the adverse event was minimal or can be appropriately managed.

RESISTANCE, VIRAL GENOTYPING, PHENOTYPING, AND VIRAL FITNESS

CASE 76-2, QUESTION 2: Will viral genotyping and phenotyping assist in selecting an appropriate therapeutic regimen for H.G.? What are these tests? What are their limitations and when should they be used? What is viral fitness, and does it have a role in clinical decision making?

Viral genotyping and phenotyping reveal resistance patterns to antiretroviral agents. Genotyping evaluates mutations in the virus's genetic material, whereas phenotyping assesses the ability of the virus to grow in the presence of increasing concentrations of antiretroviral agents. The three potential causes for the development of resistance are as follows.

1. Initial infection with a resistant isolate[111–113]
2. Natural selection of a resistant isolate as a consequence of inefficient, error-susceptible viral replication[35]

3. Generation of resistant isolates via selective pressures from antiretroviral therapies that do not fully suppress viral replication[3],[4]

Mutations are generated when naturally occurring amino acids in the HIV genome are replaced with alternative amino acids. For example, resistance to 3TC occurs when the amino acid methionine (M) is replaced by valine (V) at the 184th amino acid in the protein chain.[114],[115] This mutation is subsequently referred to as an M184V mutation. These amino acid substitutions change the proteins that are produced and may alter the shape, size, or charge of the viral enzyme's substrate or primer.[115] Subsequently, antiretroviral drug binding to the active site is decreased, affinity for natural substrates is increased, or there is an increased removal of the antiretroviral agent from the enzyme by the virus (known as pyrophosphorylation).[113] Whether a mutation results in a clinically resistant, less viable, or indifferent isolate depends on which amino acid(s) is replaced. In addition, certain mutations or combination of mutations have been shown to produce viral isolates that display increased sensitivity to various antiretroviral agents (known as hypersusceptibility). Alterations to certain key amino acids can also result in cross-resistance between various antiretrovirals.[4],[114]

Key enzymes have been extensively studied with regard to their potential for development of resistance: reverse transcriptase (RT), protease, and more recently, integrase. Replication by the RT enzyme is highly susceptible to errors. Given that the HIV genome is approximately 10,000 nucleotides in length and that mutations via the RT enzyme occur approximately once in every 10,000 nucleotides copied, it has been estimated that a mutation occurs with every viral replication cycle. With up to 10 billion particles of virus being produced per day, the potential exists for 1,000 to 10,000 mutations occurring at each site in the HIV genome every day.[35] Key mutations to the antiretroviral agents are updated periodically by expert panels of clinicians.[4]

Over time, countless viral subpopulations known as "quasi-species" develop. In any given host, at any given time, many different quasi-species can exist. In addition, within any compartment of the body (e.g., CNS, testes, lymph nodes), many different quasi-species can also exist. Because these mutant strains represent only a small number of isolates in the total viral population, they must have some replicative disadvantage when compared with the "wild-type" virus.[114] Under selective pressures from antiretroviral therapies, however, these mutant isolates can replicate. For example, if wild-type viral replication is inhibited by an antiretroviral regimen, and if any one viral strain of the quasi-species is more fit for growth in the presence of that regimen, then the viral mutant will have a competitive advantage.[114] It should be recognized that for resistance to develop, viral replication must occur. When viral replication is completely inhibited, the development of resistant isolates is unlikely.

Genotypic analysis involves sequencing the viral genetic material via PCR amplification. Mutations are identified by analysis of key sequences of the RT or protease enzymes. These tests can be rapidly processed; however, they detect mutations present only in more than 25% of all HIV isolates in the body and can only reliably detect resistance patterns in samples with HIV RNA greater than 1,000 copies/mL. Because pressures from antiretroviral therapies select resistant isolates, these tests may not provide information regarding rare, yet potentially clinically significant, isolates.[3],[4]

Phenotypic analysis involves growing virus in the presence of various concentrations of drug and then determining viral susceptibilities (e.g., half-maximal inhibitory concentration [IC_{50}]). Phenotyping is limited because it evaluates only one viral isolate at a time and could fail to identify other clinically relevant isolates.[3]

One other measure available to clinicians is “viral fitness” or “replication capacity.” The genetic changes that occur in a virus to become resistant to antiretroviral therapy often impair the virus’ ability to replicate.[116],[117] This measure is called “fitness” and is quantified as replication capacity during phenotypic evaluation. During amplification of the virus before the phenotype is measured, the replication capacity of the virus is evaluated and compared to a reference wild-type, drug-sensitive virus. A virus with normal fitness has a replication capacity between 70% and 120% of the reference viral strain; isolates with values less than 70% are considered to be less fit than wild-type virus. In general, the more mutations that occur to the virus, the more compromised the virus becomes, and the lower the fitness (although, in some situations, the interplay between mutations can result in a viral isolate that is relatively fit). Recent data have shown that, despite persistent viral replication, unfit viruses may not cause the same degree of immune destruction as fit viruses.[115] This finding is important for patients with limited treatment options because it may allow for continuation of a HAART regimen that is not completely suppressive, but that produces an unfit virus, with less T-cell depletion.

As with all clinical decisions made for those who are HIV infected, careful assessment of the results in combination with the treatment history are essential for proper clinical decision making. Consultation with an expert in antiretroviral drug resistance patterns is highly recommended.

Given H.G.’s extensive antiretroviral drug history and his current failure, a genotype or phenotype will likely provide some insights into potential therapeutic options.

SPECIAL CIRCUMSTANCES

Poor CD4 Cell Recovery

CASE 76-2, QUESTION 3: H.G. was started on a regimen of tenofovir alafenamide, emtricitabine, dolutegravir, and darunavir boosted with ritonavir. During the following 6 months, H.G.’s T-cell counts increased to 325 cells/μL and his viral load value declined to 5,000 copies/mL. At the last two clinic visits, H.G.’s viral load (copies/mL) and CD4 counts (cells/μL) were 2,000/275 and less than 20/225, respectively. H.G. reports no new clinical complaints or adverse drug events. In addition, H.G. states that he has been compliant with therapy. Are changes to therapy necessary?

In most cases, declines in viral load result in increases in CD4 cell counts; however, in some cases, CD4 cells fail to recover with

---

viral load suppression.[5] In this situation, it may be wise to continue current treatment and monitor the patient closely. Adding an additional drug to intensify the regimen or changing to a different ART regimen does not consistently increase the CD4 cell count and is not recommended.[3]

Therapeutic Drug Monitoring

Pharmacokinetic evaluations of various antiretrovirals have shown interpatient variability in drug exposures among cohorts of patients taking the same dose of drug under the same conditions.[3],[117–120] Many factors contribute to interpatient variability in drug exposure, such as pharmacogenetics, environment, different physiologic conditions, regimen adherence, and drug interactions. For most antiretrovirals, a drug exposure–response relationship exists (e.g., the higher the exposure, the faster and more prolonged the viral suppression). In addition, most antiretrovirals also have well-defined exposure–toxicity relationships.

Therapeutic drug monitoring (TDM) is currently recommended for selected clinical situations.[3],[119] For patients with uncharacterized drug interactions and those with impairments in gastrointestinal, hepatic, or renal function, drug concentrations may help identify low or high exposure that can be corrected with a dosage adjustment. TDM may also be useful for assuring that a novel antiretroviral combination or dose does not have any unpredictable adverse drug interactions. In treatment-experienced patients, knowledge of drug exposure with viral susceptibility may assist in designing an optimal dosage regimen. Conversely, patients experiencing toxicities thought to be concentration-dependent (e.g., neuropsychiatric effects of efavirenz) may benefit from TDM. Monitoring adherence and evaluating pharmacokinetics in special populations, such as pregnant women or pediatric patients, are additional indications for TDM.

Pharmacology experts currently recommend obtaining trough concentrations immediately before the next antiretroviral dose. For efavirenz (which is usually taken in the evening), samples obtained 12 hours post-dose will closely reflect the concentration at 24 hours post-dose because of its long half-life. Many factors can affect the trough values of various antiretroviral agents. For proper interpretation of the concentrations, patients should provide a dosing history from the last several days, a list of concomitantly administered drugs to screen for interactions, and the exact time the last dose was taken. The exact time the TDM sample was collected should also be recorded. Another factor that can affect interpretation of drug concentrations over time is intrapatient variability. Outside of a clinical study, where patients take their medications under conditions that vary from day to day, the concentrations could be highly variable at clinic visits over time, and several samples might be required to determine trends in the drug exposure before making a dose adjustment.Finally, to minimize laboratory variability and error in measuring these concentrations, it is also recommended that a laboratory that routinely measures antiretrovirals and participates in both internal and external quality control programs be used. A list of such laboratories can be obtained from the Clinical Pharmacology Quality Assurance and Quality Control Program (**https://www.fstrf.org/apps/cfmx/apps/cpqa/cpqaDocs/public/index.html**).

Drug Interactions

CASE 76-3

QUESTION 1: J.F. is a 37-year-old HIV positive man who has been taking emtricitabine, tenofovir disoproxil fumarate, and darunavir boosted with ritonavir for the past 4 years. His most recent lipid panel showed markedly elevated triglycerides, LDL, and total cholesterol. What needs to be considered when starting a lipid lowering medication for J.F.?

Drug interactions are very common with antiretrovirals and need to be considered when changing HIV-related or non-related drug regimens. In this case, ritonavir will significantly increase the concentrations of HMG-CoA reductase inhibitors that are metabolized by CYP3A4 through inhibition of the CYP3A4 isoenzyme.[3] If increased concentrations of the HMG-CoA reductase inhibitor could put J.F. at risk for myalgia and rhabdomyolysis. J.F.'s lipids require treatment with an HMG-CoA reductase inhibitor, one that is only partially metabolized by CYP3A4 or metabolized by another pathway should be considered. Simvastatin and lovastatin are contraindicated in combination with ritonavir, but pravastatin, pitavastatin, rosuvastatin, and atorvastatin can be used at reduced doses.[3] The DHHS HIV adult treatment guidelines have extensive tables outlining specific drug interactions and recommendations for concomitant use of medications with the antiretrovirals.[3] Table 76-6 gives the general metabolism and transport effects of each of the classes of antiretrovirals and gives an idea of the drug interaction potential of each class.

Pregnancy and Breast-Feeding

CASE 76-4

QUESTION 1: T.D. is a 32-year-old woman infected with HIV, whose antiretroviral therapy includes the combination tablet dolutegravir/abacavir/lamivudine once daily. Her virus is fully suppressed and her CD4 cells count is 786/μL. She has had a positive home pregnancy test result. Is her current antiretroviral regimen appropriate for use during pregnancy and for prevention of mother-to-child transmission?

The current perinatal HIV guidelines[121] recommend that women receiving and tolerating a currently suppressive regimen when they become pregnant continue on that regimen. The guidelines state that "In general, the same regimens as recommended for treatment of non-pregnant adults should be used in pregnant women unless there are known adverse effects for women, fetuses, or infants that outweigh benefits." Efavirenz is the only antiretroviral that is currently pregnancy category D and is not recommended during the first 8 weeks of pregnancy. It has been shown to be teratogenic in animal studies, particularly in the first trimester of pregnancy, and retrospective case reports of neural tube defects in humans have been documented.[122–125] Perinatal transmission prevention guidelines recommend abacavir/lamivudine, emtricitabine/tenofovir disoproxil fumarate or lamivudine with tenofovir disoproxil fumarate as first-line NRTIs for HAART initiation in pregnancy. Atazanavir/ritonavir and daruanvir/ritonavir are the recommended PIs for initiation in pregnancy, and raltegravir is the first integrase inhibitor to be considered preferred for initiation in pregnancy. Alternative agents for initiation in pregnancy include zidovudine/lamivudine, lopinavir/ritonavir, efavirenz as long as it is initiated after 8 weeks of pregnancy, and rilpivirine.[120] Many of the pregnancy recommendations are based on those drugs which have the most safety and efficacy data available during pregnancy (both animal and human).[122]

In women who have a viral load persistently greater than 1,000 copies/mL, it is recommended that a planned 38-week cesarean section be performed to reduce the risk of mother-to-child transmission. In women with a viral load less than 1,000 copies/mL, there is little evidence to show that cesarean section decreases transmission rates compared to vaginal delivery. In this case, the decision is made at the discretion of the physician in consultation with the mother. Additionally, if the mother's viral load is >1,000 copies/mL or unknown at the time of delivery, it is recommended that intravenous zidovudine be administered to the mother at 2 mg/kg intravenously (IV) for 1 hour at the onset of labor, then given as a continuous infusion of 1 mg/kg/hour during the intrapartum period (during labor and postpartum). Once delivered, it

is recommended that oral zidovudine at 2 mg/kg every 6 hours be started in all HIV-exposed infants immediately after birth and continued for 6 weeks. It is recommended that the infant undergo diagnostic virologic testing using either HIV DNA PCR or RNA virologic assays at a minimum at ages 14 to 21 days, 1 to 2 months, and 4 to 6 months. Antibody testing should not be performed on the infant because maternal HIV antibody crosses the placenta and will be detectable in all

HIV-exposed infants up to 18 months of age.[122]

It is not recommended that HIV-positive women breast-feed their children in resource-rich settings where clean water and formula are reasonably available. The risk of transmission from breast-feeding is consistently higher than formula feeding even with the use of antiretroviral prophylaxis.[122],[126]

Since J.F. is on a fully suppressive ARV regimen that she is tolerating, the guidelines recommend that she continue on her current regimen. If she continues to remain undetectable throughout her pregnancy, the decision whether to have a cesarean or a vaginal delivery will be at the discretion of J.F. and her physician.

Pre-Exposure Prophylaxis

CASE 76-5

QUESTION 1: F.C is a 22-year-old, HIV negative, healthy male with multiple male sex partners. He reports using condoms most of the time, but would like additional protection against the acquisition of HIV. What prevention methods can be offered to F.C.?

Pre-exposure prophylaxis (PrEP) is the use of antiretrovirals in HIV-uninfected individuals to prevent HIV infection. The fixed dose combination of emtricitabine 200 mg /tenofovir disoproxil fumarate 300 mg has been FDA approved for use as PrEP in HIV-uninfected individuals at high risk of HIV infection.[127] The Clinical Practice Guidelines for Preexposure Prophylaxis for HIV Prevention in the United States recommend PrEP as one prevention option for sexually active adult men who have sex with men, adult heterosexually active men and women, and adult injection drug users at substantial risk of HIV acquisition.[128] Additionally, the guidelines recommended that PrEP be discussed with HIV-uninfected heterosexual women and men whose partners are HIV infected as one of several options to protect the uninfected partner during conception and pregnancy. HIV testing should be done immediately before emtricitabine/tenofovir disoproxil fumarate is prescribed for PrEP and every 3 months while on emtricitabine/tenofovir disoproxil fumarate. If a patient is found to be HIV infected, emtricitabine/tenofovir disoproxil fumarate should immediately be stopped to avoid the development of resistance to emtricitabine and tenofovir. PrEP should always be provided in conjunction with behavioral risk reduction support and medication adherence counseling. In addition to regular HIV testing and risk reduction counseling, renal function testing should be performed at baseline, 3 months, and then every 6 months thereafter and sexually transmitted infections (STIs) should be screened for at baseline and every 6 months.[128]

Emtricitabine/tenofovir disoproxil fumarate one tablet daily can be considered for F.C. for the prevention of HIV. He will need to have baseline HIV, STI, and renal function testing as well as medication adherence and behavioral risk reduction counseling. He will need to follow up 3 months after emtricitabine/tenofovir disoproxil fumarate if prescribed for monitoring and repeat HIV testing.

Postexposure Prophylaxis

CASE 76-6

QUESTION 1: L.T. is a 47-year-old nurse at an HIV clinic. While drawing routine labs on a newly diagnosed HIV+ male patient, not yet started on HAART, she accidently stuck herself with a contaminated needle. Are interventions available to prevent L.T. from contracting HIV from the needlestick? What drugs should be utilized, and for how long?

Postexposure prophylaxis (PEP) is the use of ARVs to prevent HIV infection in individuals who have had an exposure to blood or body fluid either known to be infected with HIV or potentially infected with HIV. Occupational exposures require immediate evaluation with a first dose of ARVs offered within the first 2 hours following exposure.[129],[130] PEP is more effective the earlier it can be initiated, and it should always be started within 72 hours of exposure. Percutaneous exposure poses more of a concern than mucous membrane exposure. A needle stick with a large hollow-bore needle is higher risk than a solid needle, a deep penetrating wound is considered a high-risk exposure compared to a superficial injury, and a exposure to a large volume of infectious fluid is more concerning than exposure to a low volume. Patient-specific factors must also be considered, such as whether the HIV-positive patient is on HAART therapy and has a suppressed viral load or whether the HIV-positive patient currently has a high viral load. Regardless of the type of exposure or risk factors, current guidelines recommend that PEP be offered to all health care workers with an exposure. If the source patient is known to be HIV positive or the HIV status is not known, PEP should be continued for a total of 4 weeks, or 28 days. If the source patient's status is unknown but is later determined to be HIV negative, then PEP can be discontinued prior to 28 days.[129],[130]

Three-drug PEP is recommended for all health care workers exposed or possibly exposed to HIV. Recommended regimens include two NRTIs with either raltegravir or dolutegravir. Alternative regimens include two NRTIs with a boosted PI.[130]

In instances where the source patient is a known treatment experienced patient with HIV, the choice of agents to use for PEP is generally dependent on the patient's regimen and resistant profile.[129],[130]

L.T. should start immediately a PEP regimen, preferably emtricitabine/tenofovir disoproxil fumarate once daily with raltegravir twice daily or dolutegravir once daily. This entire regimen should be continued for a total of 4 weeks. It would also be a good idea to look at the specific patient from which the exposure occurred. If he had a great deal of known antiretroviral drug resistance, then L.T. may need to be put on different antiretrovirals according to the patient's resistance profile. HIV antibody testing using ELISA should be performed on L.T. at baseline exposure, 6 weeks, 12 weeks, and 6 months after exposure. She should also have baseline and follow-up labs performed to assess antiretroviral toxicity. At a minimum, these should include a complete blood count, renal and hepatic function tests, and fasting glucose while on the protease inhibitor. Additional laboratory tests should be performed based on the individual drugs chosen.[129],[130]

Additional guidelines exist for non-occupational HIV exposures and follow similar risk and stratification treatment paradigms. In those instances where a person seeks care within 72 hours of exposure to blood, genital secretions or other potentially infected body fluids of persons known to be HIV-infected and the exposure represents a substantial risk for HIV transmission then the person is started on PEP in a similar fashion as with an occupation exposure and continued for 4 weeks with similar monitoring and HIV testing.[131]

KEEPING CURRENT

The management of HIV infection continues to evolve. Additional important emerging data are in HIV prevention and cure.

The overwhelming data presented at scientific meetings and in journals have made staying informed about current issues and new developments a daunting task. As a result, many clinicians, even those actively caring for patients who are HIV infected, remain cautious and often confused regarding therapeutic options.

New technologies for the dissemination of medical information are constantly evolving. The Internet has allowed clinicians worldwide to exchange ideas, teach new concepts, and obtain access to limited resources. In addition, many research centers, patient advocacy groups, and academic institutions have posted sites on the Internet that have resulted in access to large amounts of high-quality medical information. This new technology has also allowed, however, for the dissemination of incomplete, misleading, or inaccurate information. Therefore, clinicians must remain cautious and carefully evaluate the information obtained from various websites.

When evaluating the quality of a website, clinicians should look for a few basic standards.

- Author qualifications. Is the author qualified to write the article or perform the research? Is his or her affiliation or relevant credentials provided?
- Attribution. Are references provided to confirm statements? Is all relevant copyrighted information noted?
- Currency. When was the content posted? Is the website updated regularly?
- Disclosure. Who owns the website? Is there a conflict of interest between what is being posted and any commercial interest?

Any Internet site that fails to meet these basic competencies should be viewed with caution. In general, the most accurate and informative websites for HIV-specific information come from academic institutions, government organizations, medical societies, and patient advocacy groups. Table 76-7 lists high-quality websites that provide timely and accurate information. A periodic evaluation of these sites often provides sufficient information to stay up-to-date on current issues and controversies.

CONCLUSION

Given the significant advances in antiretroviral therapy over the past 30 years, HIV-1 infection is now a manageable chronic disease for those who have access to antiretroviral therapies. The pharmacologic management of HIV continues to rapidly evolve, but a basic understanding of viral pathogenesis and drug interactions provides a framework that can be used to evaluate new information as it becomes available. Although a cure is still out of reach, methods for preventing infection via treatment as prevention, PrEP, PEP, and through the prevention of perinatal transmission, have become increasingly effective as alternative strategies for curbing the epidemic.

Opportunistic Infections in HIV-Infected Patients

Emily L. Heil and Amanda H. Corbett

CORE PRINCIPLES	CHAPTER CASES
① Acquired immunodeficiency syndrome (AIDS) is characterized by the gradual erosion of immune competence and the development of opportunistic infections (OIs) and malignancies. A decline in OIs and OI-related malignancies has been observed, which is associated with highly active antiretroviral therapy (HAART).	
② Pneumocystis jiroveci pneumonia (PCP) should be treated with trimethoprim–sulfamethoxazole (TMP-SMX). The patients intolerant of sulfonamides should be treated with alternatives such as dapsone, atovaquone, or pentamidine. Steroids should be used to treat patients with moderate-to-severe diseases. Primary prophylaxis with these agents is recommended for patients with CD4 counts less than 200.	**Case 77-1 (Questions 1-5)**
③ Toxoplasmosis typically occurs in patients with CD4 counts less than 100, and primary prophylaxis is indicated in these patients who are also Toxoplasma immunoglobulin G (IgG)-positive. Alternatives for prophylaxis include TMP-SMX, dapsone + pyrimethamine + leucovorin, and atovaquone ± pyrimethamine + leucovorin. Treatment options include sulfadiazine + pyrimethamine + leucovorin, clindamycin + pyrimethamine + leucovorin, and TMP-SMX.	**Case 77-2 (Questions 1, 3, and 4)**
④ Cytomegalovirus (CMV) typically causes retinitis in human immunodeficiency virus (HIV)–infected patients with CD4 counts less than 50. Primary prophylaxis is usually not indicated, and treatment options include intravenous (IV) ganciclovir, valgancyclovir, IV foscarnet, IV cidofovir, and intraocular ganciclovir implants.	**Case 77-3 (Questions 1 and 2)**
⑤ Cryptococcal meningitis occurs typically in patients with CD4 counts less than 50, and primary prophylaxis is not typically recommended. First-line treatment includes amphotericin + flucytosine for induction therapy with subsequent addition of fluconazole for maintenance.	**Case 77-4 (Questions 1–5, 8)**
⑥ Mycobacterium tuberculosis infects HIV-infected patients at any CD4 count, sometimes with an atypical presentation. Isoniazid for 9 months is the preferred regimen for latent tuberculosis (TB) in HIV-infected patients. Initial treatment in drug-susceptible TB is with rifampin (or rifabutin) + isoniazid + pyrazinamide + ethambutol.	**Case 77-5 (Question 1),** **Case 77-6 (Question 1), and** **Case 77-7 (Question 1)**
⑦ Mycobacterium avium complex (MAC) can be localized to the lung or	**Case 77-8 (Questions 1, 5,**

with disseminated infection in HIV-infected patients with CD4 counts less than 50. Primary prophylaxis is indicated with either azithromycin or clarithromycin. First-line treatment for acute infection consists of clarithromycin (or azithromycin) + ethambutol ± rifampin (or rifabutin).	**and 7)**

INTRODUCTION

The AIDS is characterized by the gradual erosion of immune competence and the development of OIs. Since the advent of HAART, AIDS-related mortality has declined in the United States.[1],[2] The overall 5-year survival probability after the first OI diagnosis has increased dramatically from 7% in the pre-HAART to 65% in the HAART era.[3] This decline in mortality has been associated with a decline in OIs and an increase in noninfectious AIDS-related mortality.[4] Patients with HIV infection are susceptible to an array of diseases, but most OIs are caused by a few common pathogens, including P. jiroveci (carinii), CMV, fungi, and mycobacteria.[5]

The revised classification system for HIV infection and expanded surveillance case definition for AIDS included stratification for the CD4 lymphocyte count, as well as subgrouping by clinical categories (see Chapter 76, Pharmacotherapy of Human Immunodeficiency Virus Infection, Tables 76-1 and 76-2). These AIDS-defining OIs may also occur in asymptomatic HIV-infected patients.[5]

The Natural History of Opportunistic Infections

THE DECLINE OF THE CD4 LYMPHOCYTE

Within the immune system, the CD4 lymphocyte functions as a "helper cell" that modulates the actions of the other key cellular components of the immune system. The eventual loss of CD4 lymphocytes is the underlying pathophysiology that leads to AIDS. (See Chapter 76, Pharmacotherapy of Human Immunodeficiency Virus Infection, and comprehensive immunology texts for a more detailed explanation of immune function and inflammation associated with HIV infection.) The infected CD4 lymphocyte can function normally for a time but eventually becomes dysfunctional, as manifested by an abnormal response to soluble mitogens. It is this cellular functional deficit, compounded by the eventual decline in the absolute number of CD4 lymphocytes which leads to OIs and neurologic dysfunctions. The CD4 lymphocyte count declines gradually during several years in the untreated HIV- infected person. The average rate of decline in CD4 lymphocyte cells (CD4 slope) is approximately 40 to 80 cells/μL/year in the absence of antiretroviral therapy. An accelerated decline in the CD4 count occurs at 1.5 to 2 years, just before an AIDS-defining diagnosis.[6] Without therapy, the course of infection averages approximately 10 years from the time of initial infection to an AIDS-defining diagnosis.

The CD4 count dictates the need for OI prophylaxis, influences the differential diagnosis of the OI, and is an independent indicator of prognosis. For these reasons, the CD4 count has become a primary surrogate marker of immune suppression and antiretroviral activity. HIV-1 ribonucleic acid (RNA) is the other clinical surrogate marker, most predictive of survival and antiretroviral activity.

OIs range from relatively minor events (e.g., oral candidiasis or oral hairy leukoplakia) to sight-threatening episodes of CMV retinitis or life-threatening PCP. The risk for specific OIs varies with the degree of immunosuppression.[7] Asymptomatic patients with moderate immunosuppression (CD4 counts, 200–500) may become infected with herpes viruses and Candida species or develop pneumonia, enteric infection, and meningitis with more common pathogens. Massive destruction of the immune system occurs when the CD4 count drops below 200, which increases the risk of opportunistic pathogens (e.g., PCP), opportunistic tumors, wasting, and neurologic complications. With a CD4 count of 50 to 100, invasive candidiasis, cerebral toxoplasmosis, cryptococcosis, and various protozoal infections are observed. When the CD4 count falls below 50, the patient is in an advanced immunosuppressed state, which is associated with non-Hodgkin lymphoma, CMV, and disseminated MAC (Fig. 77-1). Without treatment, the median survival associated with a CD4 count less than 200 is 3.1 years, and the time to an AIDS-defining infection ranges from 18 to 24 months.[7] With the implementation of HAART, the 3-year probability of AIDS has dramatically declined; however, much of this decline may be associated with the use of OI prophylaxis.[8]

THE EFFECT OF OPPORTUNISTIC INFECTIONS ON VIRAL LOAD AND SURVIVAL

Acute OIs upregulate HIV replication, resulting in higher HIV-1 RNA concentrations in the plasma and lymphoid tissues of HIV-infected patients. This enhanced replication is presumably caused by antigen-mediated activation of HIV-1 replication in latently infected cells. To assess the impact of OIs on survival, data from a cohort of 2,081 HIV-infected patients followed up (in the pre–protease inhibitor era) for a mean of 30 months were analyzed.[9] CD4 counts and incidence of opportunistic disease were used as independent variables. These investigators found that PCP, CMV, MAC, esophageal candidiasis, Kaposi sarcoma (KS), non-Hodgkin lymphoma, progressive multifocal leukoencephalopathy (PML), dementia, wasting syndrome, toxoplasmosis, and cryptosporidiosis were independently associated with death.[9] Additionally, data from a prospective longitudinal study of HIV infection in homosexual men initiated in 1984 (Multicenter AIDS Cohort Study) demonstrated that plasma HIV-1 RNA concentrations strongly predict the rate of decline in the absolute CD4 count as well as clinical progression to AIDS and death.[10] More recent investigations in the era of HAART have demonstrated that CD4 count is the strongest prognostic factor in patients starting therapy.[8]

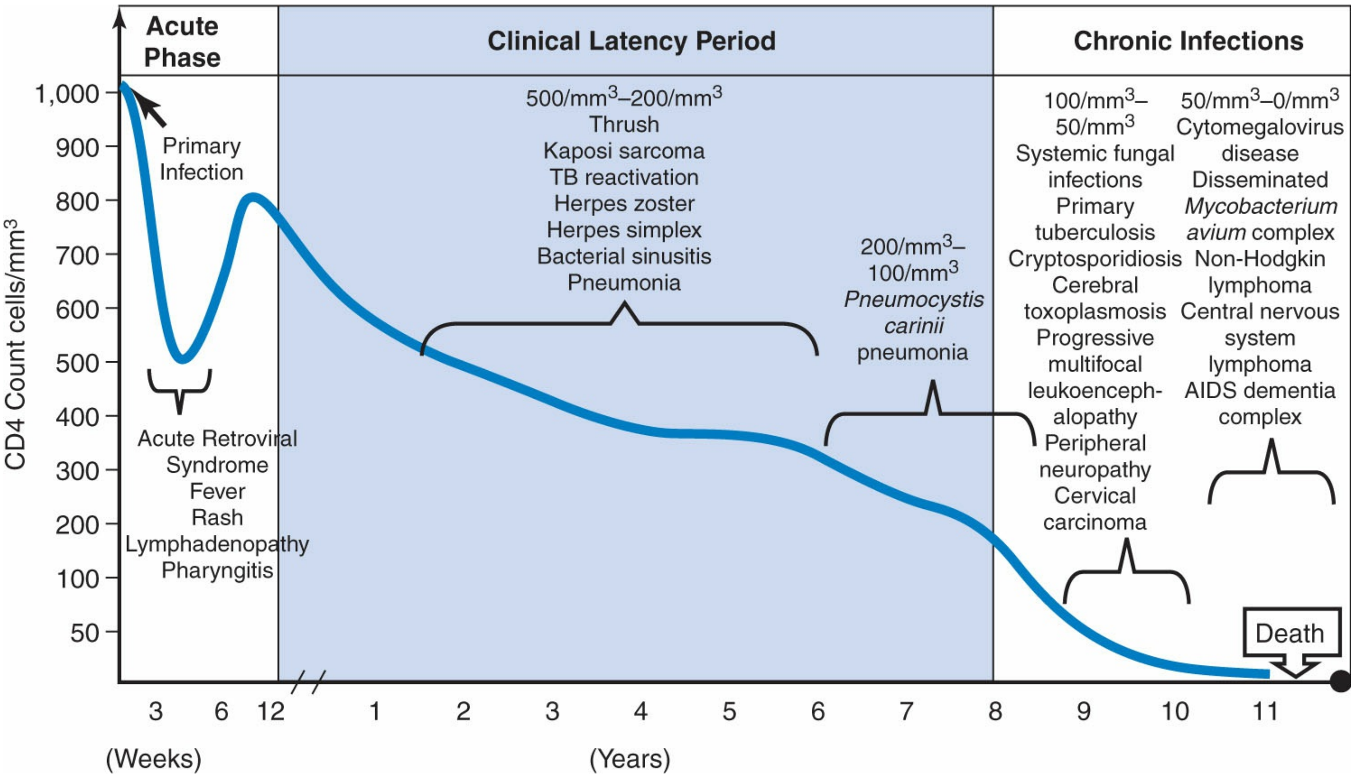

Figure 77-1 Natural history of CD4 cell count in the average HIV-infected patient without antiretroviral therapy, from the time of HIV transmissions to death. (Illustration by Mary Van, PharmD.)

IMPACT OF ANTIRETROVIRAL AGENTS ON THE NATURAL HISTORY OF OPPORTUNISTIC INFECTIONS

Reduction in the Incidence of Opportunistic Infections and Death

The introduction of protease inhibitors, combination therapy, prophylaxis therapy, and improved medical care has reduced the incidence of OIs and death resulting from AIDS in HIV-positive patients. HAART generally refers to an antiretroviral regimen that can be expected to reduce the viral load in antiretroviral-naïve patients to less than 50 copies/mL. A panel of experts convened by the US Department of Health and Human Services and the Henry J. Kaiser Family Foundation recommended HAART as the standard of care for all HIV-infected patients.[11] These potent antiretroviral agents and effective management of OIs have led to an improved quality of life and prolonged survival among HIV-infected US patients.[12] A significant decrease in the incidence of OIs and death was first reported in 1996, when preliminary data demonstrated that the addition of ritonavir to an existing reverse transcriptase regimen in severely immunocompromised patients decreased the incidence of OIs and death.[13] The steepest declines in the incidence of AIDS-defining OIs followed this introduction of HAART, but the declines have also continued into the late-

HAART area.[14] A recent analysis demonstrated both a decline in opportunistic infections (89–13.3 per 1,000 person-years) and opportunistic malignancies (23.4–3.0 per 1,000 person-years) from 1994 to 2007.[2]

CHANGES IN THE NATURAL HISTORY OF OPPORTUNISTIC INFECTIONS

OIs result from long-standing immunosuppression from HIV infection.[7] For example, before HAART, approximately 40% of all AIDS patients exhibited CMV retinitis, with the most cases occurring at CD4 counts below 100. Since the implementation of HAART, a decrease in the incidence and progression of CMV retinitis have been noted.[15],[16]

Ironically, HAART has also been associated with a worsening or an unmasking of occult OIs in patients with an advanced stage of AIDS. When antiretroviral therapy strengthens the immune system, inflammatory symptoms in response to infection are more clinically pronounced.[12] This syndrome has been referred to as immune reconstitution inflammatory syndrome (IRIS). IRIS incidence is estimated to be 10% to 40% in patients starting antiretroviral therapy, based primarily on retrospective observational data.[17–20] During IRIS, there is typically a rapid increase in CD4 lymphocytes; however, this does not represent fully functional cells, but rather an increase in memory subtypes.

The initiation of HAART typically results in an increase in CD4 lymphocytes and a decrease in HIV-1 RNA to undetectable levels. This initial increase in CD4 T cells after the initiation of therapy involves an increase in memory T cells with low proliferation and a decrease in functional or effector cells. As a result, opportunistic infections that are present in tissues are allowed to proliferate once the immune system is recovering, allowing IRIS to occur.[21]

IMPROVEMENT IN OR RESOLUTION OF OPPORTUNISTIC INFECTIONS

With the initiation of HAART, reports of improvement in or resolution of some OIs can occur.[22–26] These OIs include KS,[26] PML,[24] CMV,[15],[16] microsporidiosis, cryptosporidiosis,[23] and molluscum contagiosum,[25] a viral infection caused by a member of the Poxviridae family. Furthermore, there are reports of restored immunity and clinical improvement in patients with chronic hepatitis B infection (not classified as a CDC-defined AIDS indicator condition) with the initiation of HAART.[22] However, these infections were not eradicated, and in some cases, improvement was only transient. Clinical resolution most likely results from immunologic improvement, and the protective immunity against OI is sustained only as long as HAART remains effective.

Pharmacotherapeutic Management of Opportunistic

Infections

Successful pharmacotherapeutic management of OIs requires an understanding of the natural history of HIV-associated OIs, including the recognition that OIs occur with declining CD4 lymphocyte counts, the clinical presentation of each disease, diagnostic techniques, and effective treatment and preventive strategies. Management issues, complicated by multiple-drug therapy for OIs and HIV suppression, include adherence, toxicities, resistance, drug interactions, and cost. HIV-infected patients are usually less tolerant to drugs such as flucytosine, TMP-SMX, and pyrimethamine; however, alternative agents are available to overcome these barriers to treatment.

In 1995, the US Public Health Service (USPHS) and the Infectious Diseases Society of America (IDSA) issued guidelines for the prevention of OIs in HIV-infected patients; these were revised in 1997,[27] 1999,[28] and 2002.[29] Recommendations are included for preventing exposure to opportunistic pathogens, preventing first episodes of disease by chemoprophylaxis or vaccination (primary prophylaxis), and preventing disease recurrence (secondary prophylaxis). Additionally, in 2004, the CDC published the first edition of guidelines for the treatment of OIs.[30] In 2009, a combined set of guidelines for both prevention and treatment of more than 30 opportunistic infections was developed.[12] The most recent and any archived guidelines can be found at www.aidsinfo.nih.gov.

PRIMARY PROPHYLAXIS

Primary prophylaxis is defined as a therapy that is initiated before the appearance of an OI in high-risk asymptomatic persons to prevent the initial occurrence of an infection. Primary prevention of OIs is important, considering the inevitable immune depletion associated with chronic HIV infection.[31] PCP and MAC prophylaxis have significantly prolonged survival and delayed the onset of illness (see Prophylaxis sections for both PCP and MAC).[32],[33]

The guidelines strongly recommend primary prophylaxis against PCP, toxoplasmosis, M. tuberculosis, and MAC. Vaccinations to prevent Streptococcus pneumoniae, hepatitis B virus, hepatitis A virus, varicella zoster virus (VZV), and influenza virus infection are generally recommended for all HIV-infected patients. Primary prophylaxis for fungal infections (Cryptococcus neoformans and Histoplasma capsulatum), CMV, and bacterial infections are not routinely recommended for most patients, except in unusual circumstances (Table 77-1).

Discontinuation of Primary Prophylaxis Therapy

HAART has diminished the incidence of several OIs.[16],[23],[26] Therefore, it may be possible to discontinue prophylactic OI therapy when CD4 counts rise above the threshold associated with the risk for infection. These data have been particularly encouraging in patients who had PCP prophylaxis discontinued with an increase in CD4 counts.[12] In one observational PCP prophylaxis study, no episodes of PCP were observed after the discontinuation of primary and secondary PCP prophylaxis.[34] These studies suggest that patients who respond to HAART with a sustained increase in CD4 count can have their primary prophylaxis safely discontinued. The OI prophylaxis guidelines suggest that primary PCP prophylaxis may be discontinued for patients on HAART when the CD4 count is greater than 200 for at least 3 months. Primary prophylaxis for MAC may also be discontinued when the CD4 count increases to greater than 100.[12] In addition, the guidelines suggest discontinuing primary prophylaxis for toxoplasmosis when the CD4 count increases to greater than 200 for at least 3 months.[12]

Table 77-1

Primary Prophylaxis of Opportunistic Infections in HIV-Infected Adults and Adolescents

	Preventive Regimens			
Pathogen	**Indication**	**First Choice**	**Alternatives**	**D/C Prophylaxis**
Strongly Recommended as Standard of Care				
Pneumocystis jiroveci (carinii)	CD4 count <200 or oropharyngeal candidiasis	TMP-SMX, 1 DS PO daily or TMP-SMX 1 SS PO daily	TMP-SMX 1 DS TIW Dapsone 50 mg BID or 100 mg/day; dapsone 50 mg daily + pyrimethamine 50 mg QW + leucovorin 25 mg PO QW; aerosolized pentamidine 300 mg QM via Respirgard II nebulizer, atovaquone 1,500 mg PO daily; atovaquone 1,500 mg PO + pyrimethamine 25 mg PO + leucovorin 25 mg PO daily	Patients on HAART with sustained CD4 >200 cells for ≥3 months may discontinue PCP prophylaxis. Reintroduce if CD4 <200.
Mycobacterium tuberculosis				
Isoniazid-sensitive	+ Diagnostic test for TB with no evidence of active TB, no prior treatment OR – Diagnostic test for TB, close contact with person with active TB and no personal active TB OR History of untreated or inadequately treated TB and no evidence of active TB	Isoniazid 300 mg PO daily OR isoniazid 900 mg PO BIW × 9 months both with pyridoxine 50 mg PO daily	Rifampin 600 mg PO daily × 4 months or rifabutin dose adjusted for antiretroviral therapy × 4 months	

Drug-resistant TB	Same; high probability of exposure to isoniazid-resistant tuberculosis	Choice of drugs requires consultation with public health authorities	None	
Toxoplasma gondii	IgG antibody to Toxoplasma and CD4 count <100	TMP-SMX, 1 DS PO daily	TMP-SMX, 1 SS PO daily; TMP-SMX 1 DS PO TIW; dapsone 50 mg PO daily + pyrimethamine 50 mg PO QW + leucovorin 25 mg PO QW; dapsone 200 mg PO QW + pyrimethamine 75 mg PO QW + leucovorin 25 mg PO QW; atovaquone 1,500 mg PO daily with or without pyrimethamine 25 mg PO daily + leucovorin 10 mg PO daily	Patients on HAART with sustained CD4 >200 for ≥3 months may discontinue toxoplasmosis prophylaxis. Restart if CD4 <100–200
MAC	CD4 count <50 after ruling out active infection	Azithromycin, 1,200 mg PO QW; clarithromycin 500 mg PO BID; azithromycin 600 mg PO BIW	Rifabutin, 300 mg PO daily	Patients on HAART with sustained CD4 >100 for ≥3 months may discontinue MAC prophylaxis. Restart if CD4 <50
VZV	Preexposure prevention: Patients with CD4 ≥200 who have not been vaccinated, have no history of varicella or herpes zoster or who are seronegative for VZV Postexposure prevention: Significant exposure to chicken pox or shingles for patients who are susceptible	Preexposure: Primary varicella vaccination, two doses administered 3 months apart Postexposure prevention: VZIG 125 international units per 10 kg (maximum of 635 international units) IM administered 96 hours after exposure		
Usually Recommended				

Streptococcus pneumoniae	Regardless of CD4 count followed by: If CD4 >200 If CD4 <200 For individuals who have previously received	PCV13 0.5 mL × 1 PPV23 0.5 mL IM at least 8 weeks after PCV13 PPV23 can be offered at least 8	None	

	PPV23	weeks after receiving PCV13 or can wait until CD4 ≥200 One dose of PCV13 should be given at least 1 year after the last receipt of PPV23		
HBV	All susceptible (anti-HBc-negative) patients	Hepatitis B vaccine three doses	None	
HPV	Females aged 13–26 years Males aged 13–26 years	HPV quadrivalent vaccine 0.5 mL IM at Months 0, 1–2, and 6 OR HPV bivalent vaccine 0.5 mL IM at Months 0, 1–2, and 6 HPV quadrivalent vaccine 0.5 mL IM at Months 0, 1–2, and 6		
Influenza virus	All patients (annually before influenza season)	Inactivated influenza vaccine per recommendation for the season (note, live attenuated influenza vaccine is contraindicated in all HIV-infected patients)		
HAV	All susceptible (anti-HAV-negative) patients at an increased risk for HAV or patients with chronic liver disease (including HBV or HCV)	Hepatitis A vaccine; two doses	None	
Not Recommended for Most Patients; Indicated for Use Only in Unusual Circumstances				
Bacteria	Neutropenia	G-CSF 510 mg/kg SC daily × 24 weeks or GM-CSF 250 mg/m^2 SC × 24 weeks	None	
Cryptococcus neoformans	CD4 count <50	Fluconazole 100–200 mg PO daily	Itraconazole 200 mg PO daily	
Histoplasma capsulatum	CD4 count <100, endemic geographic areas	Itraconazole 200 mg PO daily	None	
CMV	CD4 count <50 and CMV antibody–positive	Valganciclovir 900 mg PO daily	None	

BID, twice a day; BIW, twice weekly; CMV, cytomegalovirus; DS, double strength; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; HAART, highly active antiretroviral therapy; HAV, hepatitis A virus; HBc, hepatitis B core; HBV, hepatitis B virus; HPV, human papillomavirus; IM, intramuscularly; INH, isoniazid; MAC, Mycobacterium avium complex; PCV13, 13-valent pneumococcal conjugate vaccine; PO, orally; PPV23, 23-valent pneumococcal polysaccharides vaccine; QM, monthly; QW, weekly; RIF, rifampin; SC, subcutaneously; SS, single strength; TIW, three times a week; TMP-SMX, trimethoprim–sulfamethoxazole; TST, tuberculin skin test; VZIG, varicella zoster immune globulin; VZV, varicella zoster virus.

Guidelines for prevention and treatment of opportunistic infections in HIV-infected adults and adolescents: recommendations from CDC, the National Institutes of Health, and the HIV Medicine Association of the Infectious Diseases Society of America. https://aidsinfo.nih.gov/guidelines/html/4/adult-and-adolescent-oi-prevention-and-treatment-guidelines/.

ACUTE THERAPY

Prompt diagnosis and immediate initiation of therapy are essential for the management of acute infections. Most common OIs can be classified into one of two groups. The first group consists of infections that can be treated by conventional or investigational agents. These include PCP, TB, cryptococcosis, CMV, MAC, and histoplasmosis. Treatment may result in either effective or moderately effective resolution. These infections may recur if chronic suppressive or secondary prophylaxis is discontinued without an accompanying elevation in the CD4 count and viral load suppression. The second group includes pathogens for which no therapeutic regimen is currently effective. These include cryptosporidiosis, microsporidiosis, and PML.

SECONDARY PROPHYLAXIS OR CHRONIC SUPPRESSIVE THERAPY

Secondary prophylaxis is used to prevent recurrence of an OI once the patient has developed signs and symptoms of active infection. In some cases, secondary prophylaxis regimens can be discontinued after patients achieve a certain CD4 level. The USPHS and IDSA strongly recommend secondary prophylaxis for PCP, toxoplasmosis (reduced dosage), MAC, CMV, Salmonella species, and infections caused by endemic fungi and C. neoformans.[12]

Discontinuation of Secondary Prophylaxis or Chronic Suppressive Therapy

The USPHS/IDSA guidelines recommend discontinuing primary or secondary prophylaxis for certain pathogens with HAART-related increases in CD4 count to specified threshold levels.[12] Criteria for discontinuing chemoprophylaxis are based on specific clinical studies and vary by duration of CD4 count increase and duration of treatment of the initial episode of disease (in the case of secondary prophylaxis).

Secondary PCP prophylaxis may be discontinued among patients whose CD4 counts have increased to greater than 200 for more than 3 months while on HAART. Secondary prophylaxis for disseminated MAC may be discontinued among patients who have completed 12 months of MAC therapy, have no signs or symptoms of MAC, and have had a CD4 count of greater than 100 for more than or equal to 3 months in response to HAART. Similarly, secondary prophylaxis for toxoplasmosis may be discontinued in patients who have completed initial therapy, have no signs or symptoms of infection, and have had CD4 counts of greater than 200 for more than 3 months. Using the same criteria, patients with cryptococcosis can discontinue secondary prophylaxis if they have had CD4 counts of greater than or equal to 200 for more than 6 months. Maintenance therapy for CMV can be discontinued safely in patients who have maintained a CD4 count of greater than 100 for greater than 6 months on HAART.[12],[16] The decision to stop CMV prophylaxis should be made in consultation with an ophthalmologist and is influenced by factors such as the magnitude and duration of CD4 increases and viral load suppression, anatomic location of retinal lesions, and vision in the contralateral eye.

Although there are considerable data concerning the discontinuation of primary and secondary prophylaxis, there are no data regarding restarting prophylaxis if the CD4 count decreases again to levels at which the patient is likely to again be at risk for OIs. For primary prophylaxis, the same CD4 count threshold for stopping or restarting therapy is recommended. For PCP prophylaxis, the current guidelines use a CD4 count of 200 as the threshold for restarting both primary and secondary prophylaxis. For toxoplasmosis, the CD4 threshold is 100 to 200, and for MAC, it is 50.[12]

PNEUMOCYSTIS JIROVECI PNEUMONIA

As an indication of the relative obscurity of this organism, no comprehensive text on PCP was available until 1983.[35] Since that time, this organism has been reclassified from a protozoan to a fungus on the basis of ribosomal RNA sequence comparisons. The morphologic resemblance of P. carinii to a protozoan has led to its life cycle being described as a cyst form, with up to eight sporozoites per cyst. The trophozoite or extracystic form has different staining characteristics (i.e., it does not stain with Toluidine Blue O or Grocott-Gomori stains) compared with the cyst or sporozoites. In addition, current literature refers to PCP as P. jiroveci as opposed to the original terminology of Pneumocystis carinii. The former species is the one responsible for infectivity in humans. P. jiroveci pneumonia is the second leading opportunistic infection affecting HIV-infected patients in the United States.[2] Hospitalizations and hospital mortality for AIDS-associated PCP have decreased significantly in the last 20 years; however, there has been a shift in the overall population at risk for PCP over time with a greater proportion of patients with PCP who are black, female, or from the southern region of the United States.[36]

Clinical Presentation

CASE 77-1

QUESTION 1: J.R. is a 38-year-old, HIV-seropositive man who was diagnosed 5 years ago when he had an outbreak of herpes zoster. He refused antiretroviral therapy and was determined to treat himself using natural teas and herbs. J.R. developed a mild, nonproductive cough that has persisted for the last 4 weeks. He has also had a low-grade fever but denies any chills or pleuritic chest pain. His chest radiograph demonstrates a diffuse, symmetric, interstitial infiltrate. Arterial oxygen partial pressure (Pao_2) is 80 mm Hg. His last CD4 count approximately 3 months ago was 180 cells/μL, and his viral load was 60,000 copies/mL. He refused primary PCP prophylaxis. After hypertonic saline nebulization for sputum induction and subsequent bronchoalveolar lavage, examination of the specimens with the modified Giemsa stain revealed both intracystic bodies and extracystic trophozoites. How is the clinical presentation of J.R. consistent with PCP?

The clinical features of PCP in AIDS patients differ from those of non-AIDS patients in that a more subtle onset, with mild fever, a cough, tachypnea, and dyspnea, is typically seen in HIV-infected patients.[12] J.R.'s low-grade fever and mild, nonproductive cough of 4 weeks' duration are consistent with this description of PCP. His history of HIV infection and the finding of trophozoites on Giemsa stain further support a diagnosis of PCP. The characteristic diffuse interstitial pulmonary infiltrates on J.R.'s chest radiograph are consistent with PCP. Limited data exist with regard to the latent state of *P. jiroveci* after host infection. Some investigators hypothesize that most persons are asymptomatic unless the host immune system becomes impaired. Others believe that the infection is caused by reinfection as opposed to reactivation.[37]

Antimicrobial Selection

CASE 77-1, QUESTION 2: A diagnosis of PCP is made and J.R. agrees to be treated. What patient factors are important to consider when selecting an antimicrobial? What would be a reasonable drug for J.R., and how might his course of PCP be monitored?

The treatment of acute PCP is determined by the degree of clinical severity on presentation. The arterial oxygen status on presentation is an important indicator of overall outcome. Key factors to consider when initiating therapy for PCP include arterial blood gas findings, whether it is an initial or repeat episode of PCP, the need for parenteral therapy, and a prior history of adverse drug reactions or hypersensitivity. Concomitant therapy must also be considered.

Patients with PCP often can be classified as having mild, moderate, or severe disease, based on their oxygenation. Patients with mild PCP often have a room air alveolar-arterial (A-a) oxygen gradient of less than 35 or Pao_2 greater than 70 mm

Hg, and patients with moderate or severe disease have an A-a greater than 35 mm Hg or Pao_2 greater than 70 mm Hg. With the advent of corticosteroid use for moderate-to-severe cases of PCP (discussed later), it is useful to calculate the A-a gradient or Pao_2. The A-a gradient (normal range, 5–15 mm Hg) can be calculated as $PIO_2 - (1.25 \times Paco_2) - Pao_2$, where PIO_2 is the partial pressure of inspired oxygen (150 mm Hg in room air), and $Paco_2$ and Pao_2 are arterial levels of CO_2 and O_2, respectively, expressed in mm Hg.

Several other clinical tests have been used to identify and monitor PCP. The lactate dehydrogenase concentration in serum or bronchoalveolar lavage fluid has been used to aid in diagnosis, monitor therapy, and to predict the outcome of PCP. However, it is a nonspecific value and should not be used alone. Chest radiographs also vary with PCP. The most common picture is one of bilateral diffuse interstitial pneumonitis, but atypical patterns, such as pleural effusion, cavities, pneumatoceles, and nodules, may also occur. A normal chest radiograph is associated with improved clinical outcome.

The natural course of PCP among untreated HIV-infected patients is progressive dyspnea and hypoxemia. Increasing patient age, subsequent episode of PCP, low hemoglobin, low partial pressure of oxygen breathing room air, the presence of medical comorbidity, and pulmonary KS are all early predictors of mortality from PCP at hospital admission.[38] The treatment of PCP in AIDS patients (compared with non–HIV-infected patients) indicates that a longer duration of therapy is needed.[35] Some patients may experience worsening hypoxemia during the first 3 to 5 days after the treatment is initiated. This period of clinical worsening is least tolerated by those patients with moderate-to-severe PCP (Pao_2 <70 mm Hg). In sicker patients, this period may lead to respiratory failure and the need for intubation. Although many would associate the need for intensive care unit admission as a poor prognostic factor, many patients do well despite the need for mechanical ventilation and IV antibiotics. In light of the role of corticosteroids, patients with PCP and respiratory failure may be viewed as manageable if treated aggressively (Table 77-2).

TRIMETHOPRIM–SULFAMETHOXAZOLE

The decision to hospitalize a patient is based on the severity of his or her illness. Patients who present with mild PCP with reasonable oxygenation and without evidence of clinical deterioration can be managed as outpatients. Patients with reasonably good gas exchange (i.e., Pao_2 >70 mm Hg) but with signs of clinical deterioration most often are admitted to the hospital and given oxygen by nasal cannula and are usually started on IV TMP-SMX (15–20 mg/kg/day TMP and 75–100 mg/kg/day SMX) for 21 days.[12,39] The dosing of IV TMP-SMX must be modified in patients with renal dysfunction. TMP reversibly inhibits dihydrofolate reductase, and sulfamethoxazole competes with para-aminobenzoic acid in the production of dihydrofolate, synergistically blocking thymidine biosynthesis.

Table 77-2

Treatment of Pneumocystis jiroveci Pneumonia

Regimen	Dose	Route	Adverse Effects/Comments
Approved			
TMP-SMX	15–20 mg/kg TMP (75–100 mg/kg SMX) daily administered IV or PO every 6–8 hours or two DS tablets TID	IV, PO	Hypersensitivity, hyperkalemia, rash, fever, neutropenia ↑LFTs, and nephrotoxicity (15 mg/kg/day preferred to 20 mg/kg/day because of reduced toxicity)
Pentamidine isethionate	4 mg/kg IV daily for 60–90 minutes × 21 days	IV	Pancreatitis, hypotension, hypoglycemia, hyperglycemia, and nephrotoxicity
Atovaquone[a]	750 mg BID with meals × 21 days (suspension)	PO	Headache, nausea, diarrhea, rash, fever, and ↑LFTs
TMP[a] + dapsone	15 mg/kg/day	PO	Pruritus, GI intolerance, and bone marrow suppression
	100 mg/day × 21 days	PO	Methemoglobinemia and hemolytic anemia (contraindicated in G6PD deficiency)
Clindamycin + primaquine	600 mg IV every 8 hours or 300–450 mg PO every 6 hours	PO or IV	Rash and diarrhea
	15–30 mg (base) daily × 21 days	PO	Methemoglobinemia and hemolytic anemia (contraindicated in G6PD deficiency)
Prednisone	Within 72 hours of anti-Pneumocystis therapy 40 mg every 12 hours × 5 days, then 40 mg daily × 5 days, then 20 mg/day × 11 days	PO	Initiation in patients with moderately severe or severe disease
			Pao_2 <70 mm Hg or A-a gradient >35 mm Hg

[a] Used only in mild to moderate Pneumocystis jiroveci pneumonia. A-a, alveolar-arterial gradient; BID, twice a day; CNS, central nervous system; DS, double strength; GI, gastrointestinal; G6PD, glucose-6 phosphate dehydrogenase; IV, intravenous; PO, oral; Pao_2, arterial partial pressure of oxygen; LFTs, liver function tests; TMP-SMX, trimethoprim–sulfamethoxazole.

TMP-SMX is the drug of choice for PCP unless the patient has a history of life-threatening intolerance. In the treatment of PCP, TMP-SMX is either as effective as or superior to all alternative agents. A good response may be expected in more than 70% of patients receiving TMP-SMX. TMP-SMX is often prescribed orally (PO) because of its high bioavailability. The usual dose is 15 mg/kg (dosed by the TMP component) divided every 8 hours for 21 days. Because one double-strength tablet of TMP-SMX contains 160 mg TMP plus 800 mg SMX, a standard regimen is two double-strength tablets 3 times per day (or every 8 hours).

Although the TMP-SMX regimen is very efficacious, 25% to 50% of patients may be intolerant. Adverse effects include an erythematous, maculopapular, morbilliform rash, and, less commonly, severe urticaria, exfoliative dermatitis, and Stevens–Johnson syndrome. GI intolerance (nausea, vomiting, and abdominal pain) is common.[12] Hematologic side effects may include leukopenia, anemia, and thrombocytopenia. Neurologic toxicities, hyperkalemia, and hepatitis may also occur. Most patients who exhibit a mild hypersensitivity (skin rash) reaction can be managed with antipruritics or antihistamines without discontinuation of TMP-SMX. In some patients with mild hypersensitivity reactions, the agent can be restarted after the rash has resolved, using gradual dosage escalation or rapid oral desensitization to reduce adverse effects.[40] Patients with severe adverse reactions should be switched to another agent rather than being rechallenged with this drug (See also Chapter 32, Drug Hypersensitivity Reactions).

Because J.R. seems to have a mild-to-moderate case of PCP (Pao_2, 80 mm Hg), has not previously experienced an episode of PCP, and has no history of adverse effects to TMP-SMX, an outpatient course of TMP-SMX would be reasonable.

ALTERNATIVES TO TRIMETHOPRIM– SULFAMETHOXAZOLE

CASE 77-1, QUESTION 3: J.R. experienced exfoliative dermatitis on Day 7 of TMP-SMX treatment. What other drugs could be prescribed to treat his PCP?

Because J.R. presents with a serious adverse effect to TMP-SMX, it should be discontinued and he should not be rechallenged or desensitized. Instead, he should be treated with an alternative regimen (Table 77-2).

IV pentamidine isethionate can be used to treat acute PCP. The mechanism of action is unknown, but it may be related to interference with oxidative phosphorylation, inhibition of nucleic acid biosynthesis, or interference with dihydrofolate reductase. Pentamidine is generally more toxic than TMP-SMX.[41] In a 5-year review of 106 courses of IV pentamidine, 76 (72%) patients had adverse reactions (nephrotoxicity, dysglycemia, hepatotoxicity, hyperkalemia, and hyperamylasemia). Drug discontinuation occurred in 31 (18%) of the severe cases. Nephrotoxicity and hypoglycemia were the most common causes of drug discontinuation. Nephrotoxicity occurred in 25% to 50% of the patients with dehydration and concurrent nephrotoxic drugs among the risk factors. Hypoglycemia was noted in 5% to 10% of patients after 5 to 7 days of treatment or several days after discontinuation of treatment. Hyperglycemia is a consequence of decreased β-cells and results in diabetes mellitus in 2% to 9% of patients. Other less common adverse effects and toxicities include thrombocytopenia, orthostatic hypotension, ventricular tachycardia, leukopenia, nausea, vomiting, abdominal pain, and anorexia.[41]

Patients receiving IV pentamidine should be monitored closely, and serum concentrations of glucose, potassium, blood urea nitrogen (BUN), and creatinine should be obtained daily or every other day during treatment. Other tests for periodic monitoring include a complete blood count (CBC), liver function tests (LFTs), amylase, lipase, and calcium.[41] Renal toxicity often responds to a reduction in the dosage of pentamidine to 3 mg/kg/day or 4 mg/kg every 48 hours (creatinine clearance <10 mL/minute); however, the drug should be discontinued in patients who exhibit signs and symptoms of pancreatitis. Risk factors for pentamidine-induced pancreatitis include prior episodes of pancreatitis and concurrent therapy with other drugs known to cause pancreatitis. Nebulized pentamidine should not be considered as an alternative to IV pentamidine for the treatment of PCP.[42]

Atovaquone suspension, 750 mg twice a day (BID), is available for the treatment of mild-to-moderate PCP. Atovaquone interrupts protozoan pyrimidine synthesis and demonstrates activity against P. jiroveci and Toxoplasma gondii in animal models. Atovaquone is approved by the US Food and Drug Administration (FDA) for the treatment of mild-to-moderate PCP in patients intolerant of TMP-SMX. Atovaquone is also an alternative for primary and secondary prophylaxis for both PCP and toxoplasmosis.[12] Atovaquone is well tolerated compared with other PCP therapies. Adverse effects include rash, fever, elevated LFTs, and emesis. Atovaquone is safer, but less effective, than TMP-SMX in patients with mild-to-moderate PCP.[43] When compared with IV pentamidine in the treatment of mild-to-moderate PCP, atovaquone and pentamidine were equally efficacious; however, pentamidine was significantly more toxic.[44] Most atovaquone studies were performed using the moderately absorbed oral tablets; reformulation of this drug as a suspension has improved bioavailability by at least 30%. Concomitant administration of fatty foods with atovaquone doubles the absorption.

An oral regimen of dapsone plus TMP is another alternative to TMP-SMX. Dapsone–TMP can be used to treat mild-to-moderate PCP in patients intolerant of TMP-SMX. Dapsone is a sulfone antimicrobial that is used for leprosy. Although monotherapy (200 mg/day) with dapsone is ineffective for the treatment (not prophylaxis) of PCP, the addition of TMP (20 mg/kg/day) to dapsone (100 mg/day) is an effective alternative regimen.[45] In a small comparative trial of TMP–dapsone versus TMP-SMX, the response rates of 93% and 90% were observed, respectively.[46] When dapsone is coadministered with TMP, the resulting plasma concentrations for both drugs are higher than when either drug is taken alone. In combination with TMP, a pyrimidine, synergistic inhibition of folic acid synthesis occurs.[47] Dapsone–TMP should not be used in sulfonamide-allergic patients with a history of type I hypersensitivity reaction, toxic epidermal necrolysis, or Stevens–Johnson syndrome. Dapsone is associated with hematologic toxicities, including hemolytic anemia, methemoglobinemia, neutropenia, and thrombocytopenia. Patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency cannot detoxify hydrogen peroxide and are at an increased risk for hematologic toxicity from dapsone.

Success rates of 70% to 100% have been reported with clindamycin (600 mg IV every 6 hours or 600 mg PO 3 times a day [TID]) given in conjunction with 30 mg/day of primaquine base. Although skin rashes are common with this combination, these often subside with continued therapy. Some patients experience toxicities (fever, rash, granulocytopenia, and methemoglobinemia) requiring discontinuation.[48–50] As with dapsone, before starting primaquine, patients should be screened for G6PD deficiency. Patients who test positive for G6PD deficiency are at a risk for developing hemolytic anemia.

A double-blind efficacy and toxicity study of 181 patients with mild-to-moderate PCP compared three oral drug regimens: TMP-SMX versus dapsone–TMP versus clindamycin–primaquine. The doses of TMP-SMX and dapsone–TMP were weight-based, and

---

the dosage of clindamycin–primaquine was 600 mg clindamycin TID and primaquine 30 mg/day. All patients with moderately severe PCP (A-a oxygen gradient >45) were treated with prednisone (40 mg BID for 5 days, then once daily for 3 weeks). Rash was the most frequent dose-limiting toxicity (TMP-SMX, 19%; dapsone–TMP, 10%; clindamycin–primaquine, 21%). Hematologic toxicities were observed more frequently in the clindamycin–primaquine arm. Elevated LFTs (5 times above baseline) were more frequent in the TMP-SMX arm. The clindamycin–primaquine group demonstrated better quality of life scores at Day 7, but by Day 21, these differences became less significant.[45] TMP-SMX, dapsone–TMP, and clindamycin–primaquine demonstrated equal efficacy in patients with mild-to-moderate PCP.

J.R. should be hospitalized to better manage his severe adverse reaction and to complete his treatment of PCP. Because of his severe reaction to TMP-SMX, dapsone–TMP should not be administered because dapsone is a sulfone with a risk of cross-reactivity in patients with severe sulfonamide allergies. IV pentamidine is an option for J.R., but its toxicity suggests that it should be reserved for patients with more severe PCP presentation. Atovaquone is a reasonable option for patients with mild PCP who are intolerant of TMP-SMX and have no evidence of GI dysfunction, but it is not as effective as TMP-SMX or IV pentamidine. Clindamycin–primaquine is as efficacious as TMP-SMX for the treatment of mild-to-moderate PCP and can be administered PO. Consequently, it is the drug of choice in this patient.

The decision was made to start J.R. on oral clindamycin–primaquine for his mild-to-moderate PCP. J.R. tested negative for G6PD deficiency and was treated with clindamycin–primaquine for 14 days, completing a 21-day course of PCP therapy (Table 77-2).

Initiation of Corticosteroids

CASE 77-1, QUESTION 4: Should J.R. receive corticosteroid therapy with PCP treatment? If so, when should corticosteroids be initiated, and what would be a reasonable regimen for patients with PCP?

Corticosteroids have an important role in the management of patients with acute PCP who are clinically ill and have a low Po_2 (<70 mm Hg) or an A-a oxygen gradient greater than 35.[12] Many patients who are started on PCP therapy have an acute period of clinical deterioration, which may be associated with an acute inflammatory reaction to the rapid killing of Pneumocystis. Particularly among patients with moderate-to-severe PCP (A-a oxygen gradient >35 mm Hg or Pao_2 <70 mm Hg on room air), the use of prednisone during the first 72 hours of treatment may prevent fatal acute deterioration.[51] Corticosteroids may also have some benefits in patients exhibiting acute respiratory failure after 72 hours of conventional PCP therapy.[52] The recommended dose of prednisone is 40 mg given PO BID for 5 days, then 40 mg/day for 5 days, and then 20 mg/day for 11 days, for a total of 21 days.[53] Patients requiring IV corticosteroids may receive methylprednisolone at 75% of the prednisone dose. The major concern using glucocorticoids is the activation of latent infections (such as TB) or exacerbation of an active undiagnosed condition (especially fungal infections). However, the beneficial role of corticosteroids as adjunctive therapy outweighs the relative risk of short-term steroid use in this population.[54] More common side effects of short-term corticosteroids include ulcerative esophagitis, increased appetite, weight gain, sodium and fluid retention, headache, and elevated LFTs. Corticosteroids should be used with caution in the presence of uncontrolled diabetes, active GI bleeding, and uncontrolled hypertension.

Considering his mild hypoxemia (Pao_2, >70 mm Hg), J.R. is not a candidate for corticosteroid therapy.

Prophylaxis

CASE 77-1, QUESTION 5: J.R. was hospitalized and responded well to treatment. He now is a candidate for secondary prophylaxis. What secondary prophylaxis would be a good choice for J.R. when he is discharged from the hospital?

The early recognized efficacy of TMP-SMX prophylaxis[49] led to the eventual widespread application of prophylaxis and the development of guidelines for PCP prophylaxis (Table 77-2).[12] HIV-infected patients not receiving HAART or Pneumocystis prophylaxis were associated with a PCP prevalence of 8.4%, 18.4%, and 33.3% at 6, 12, and 36 months, respectively, in patients with a CD4 count of less than 200.[55] These data have formed the basis on which patients receive PCP prophylaxis. In addition to patients with CD4 counts of less than 200, other patients at a risk for PCP include those with a CD4 count of less than 14%, a history of an AIDS-defining illness, a history of oropharyngeal candidiasis, and possibly those with CD4 counts of 200 to 250.[12] J.R. refused primary prophylaxis and developed PCP. Secondary prophylaxis is necessary for J.R. to prevent recurrence and should be continued for life or until immune reconstitution occurs as a result of antiretroviral therapy.

The same agents and dosing schedules are recommended for primary (before an acute event) and secondary (after an acute event) prophylaxis of PCP.[12] TMP-SMX, one double-strength tablet daily, is the most efficacious prophylactic regimen; a single-strength tablet given daily is less toxic and nearly as efficacious. Patients with a history of non–life-threatening rash or fever caused by TMP-SMX may benefit from rechallenge with the original (or half) dose, or a dose escalation technique (desensitization regimen). Desensitization is preferred to switching to an alternative agent and is more successful than the direct rechallenge method.[56] Desensitization involves initiating very low doses of TMP-SMX and gradually increasing to the maximum dose over the course of days to weeks. In addition, patients who develop PCP while receiving prophylactic doses of TMP-SMX usually respond to full therapeutic doses for acute therapy. However, J.R. had a life-threatening reaction to TMP-SMX and should not be rechallenged or desensitized, and another agent should be chosen for prophylaxis.

The alternative agents used for prophylaxis include dapsone, dapsone plus pyrimethamine (with leucovorin), atovaquone suspension, and aerosolized pentamidine administered by the Respirgard II nebulizer (Table 77-2). TMP-SMX confers additional protection against toxoplasmosis and certain bacterial infections. Regimens containing dapsone plus pyrimethamine or atovaquone with or without pyrimethamine also protect against toxoplasmosis.[12] Although yet to be confirmed in clinical trials, other options include oral clindamycin–primaquine, intermittently administered IV pentamidine, oral pyrimethamine–sulfadiazine, and aerosolized pentamidine administered by other nebulizing devices.[12] TMP-SMX is more efficacious than dapsone or aerosolized pentamidine in the prevention of PCP.[57]

Extrapulmonary (e.g., lymph nodes, spleen, liver, bone marrow, adrenal gland, and GI tract) P. carinii has been noted in patients receiving inhaled pentamidine prophylaxis,[58] a finding rarely observed with IV administration. In addition, aerosolized pentamidine alters the usual chest radiograph findings associated with PCP, potentially complicating the diagnosis of this disease. Upper lobe infiltrates, cystic lesions, pneumothoraces, cavitary lesions with nodular infiltrates, and pleural effusions have been associated with aerosolized pentamidine prophylaxis.

The guidelines for primary prophylaxis suggest that prophylactic antimicrobial therapy can be discontinued when CD4 counts rise above the threshold associated with a risk for infection (i.e., <200 for PCP).[12] Many studies support the practice of discontinuing

---

secondary PCP prophylaxis in patients whose CD4 counts have increased to greater than 200 for at least 3 months.[12] A European cohort study found that primary PCP rates were very low in patients with CD4 counts of 101 to 200 cells/µL and a viral load of less than 400 copies/mL regardless of prophylaxis, indicating that discontinuation of prophylaxis may be safe in patients with a CD4 count greater than 100 cells/µL who are on effective antiretrovirals.[59] The guidelines recommend that prophylaxis be reintroduced if the CD4 count decreases to less than 200 or if PCP recurs at a CD4 count of greater than 200.[12] J.R. responded well to his PCP treatment with clindamycin–primaquine in the hospital. However, because this regimen is unproven for secondary prophylaxis, it cannot be recommended. Considering his intolerance to TMP-SMX, the best selections would be dapsone (with or without pyrimethamine) or atovaquone suspension.

TOXOPLASMA GONDII ENCEPHALITIS

Clinical Presentation

CASE 77-2

QUESTION 1: W.O. is a 40-year-old man discovered to be HIV-positive during admission to a detoxification program for alcohol and heroin dependency. W.O. presented to the AIDS clinic with esophageal candidiasis, a CD4 count of 60 cells/µL (normal, approximately 1,000 cells/µL), a viral load of 150,000 copies/mL, and a Toxoplasma IgG titer of 1:256. W.O. was started on HAART. He remained well until 2 years later, when he presented to the emergency department reporting two seizures in the past 24 hours. His medications at that time included daily emtricitabine, tenofovir, darunavir/ritonavir, and inhaled pentamidine 300 mg monthly. His temperature was 100.1°F, and he was observed to have difficulty walking. His CD4 count is 90 cells/µL (previously 230 cells/µL), viral load is 70,000 copies/mL (previously 4,000), and white blood cell (WBC) count is 4,200 cells/L (normal, 3,800–9,800). A magnetic resonance image (MRI) of the head reveals several ring-shaped lesions in the brain stem. Toxoplasma encephalitis is presumptively diagnosed. Should W.O. be isolated from other patients and health-care workers to prevent the spread of this organism?

T. gondii is a parasitic protozoan that can infect people and is spread by environmental factors, such as the consumption of raw or undercooked meats and contact with cat feces. Immunocompetent persons infected with T. gondii may develop mild symptoms resembling infectious mononucleosis. However, these symptoms are generally transient and not associated with significant sequelae in immunocompetent patients (except in pregnant women). Recrudescent disease from T. gondii is problematic in patients with a suppressed cellular immune system, including those infected with HIV. Any HIV-positive patient infected with T. gondii is at a risk for developing clinical disease, particularly at CD4 counts less than 100, as illustrated by W.O.[12] W.O. presents with encephalitis (an inflammation of the brain or brainstem), the most frequent manifestation of T. gondii in HIV-positive patients.

All HIV-infected patients should be tested for IgG antibody to T. gondii after HIV diagnosis to detect latent infection. In the United States, as many as 70% of healthy adults are seropositive to Toxoplasma. The prevalence of Toxoplasma encephalitis among HIV-positive patients varies depending on the geographic region. In the United States, only 3% to 10% of AIDS patients actually develop encephalitis. In countries such as France, El Salvador, and Tahiti, where uncooked meat commonly is ingested, seropositivity is greater than 90% by the fourth decade of life. Toxoplasma encephalitis may develop in as many as 25% to 50% of AIDS patients in these countries.[60]

The two major routes of transmission of Toxoplasma to humans are oral and congenital. W.O. need not be isolated from other patients and health-care workers. HIV-infected patients should be advised not to eat raw and undercooked meat (internal temperature of meat should be at least 165°F–170°F), especially patients who are IgG-negative for T. gondii. Patients should wash their hands after touching uncooked meats and soil, and fruits and vegetables must be washed before eating. HIV-infected patients should avoid stray cats, keep their cats inside, and change the litter box daily. If no one else is available to change the litter box, patients should wash their hands thoroughly afterward.[12]

Diagnosis

CASE 77-2, QUESTION 2: Is there sufficient clinical evidence to establish a presumptive diagnosis of Toxoplasma encephalitis in W.O.?

The diagnosis of Toxoplasma encephalitis usually is presumptive because demonstration of cysts or trophozoites in brain tissue is required for a definitive diagnosis. The clinical signs and symptoms of Toxoplasma encephalitis can be either focal (indicating a specific region of the brain that is infected or inflamed) or generalized (indicating diffuse inflammation of the brain). Toxoplasma encephalitis usually occurs in patients with CD4 counts of less than 100. Serum titers of antibodies against T. gondii typically reflect past infection with the organism and unfortunately do not help delineate whether acute infection is present. In addition, cerebrospinal fluid (CSF) polymerase chain reaction for Toxoplasma is not always a reliable diagnostic tool. Most patients with encephalitis have single or multiple ring-enhancing lesions demonstrated on computed tomography scan or MRI of the head. Brain biopsy is reserved for patients with symptoms of encephalitis who are seronegative and for those who do not respond to presumptive antitoxoplasmosis therapy.[61] Because of the nonspecific diagnosis of Toxoplasma encephalitis, a high index of suspicion for other causes of encephalitis (e.g., central nervous system [CNS] lymphoma or TB) should be maintained throughout the treatment period for presumed Toxoplasma encephalitis. W.O. has overwhelming clinical evidence suggestive of Toxoplasma encephalitis. He is HIV-positive, has a CD4 count of less than 100, a positive Toxoplasma titer of 1:256 IgG, and a ring-shaped lesion in the brainstem on MRI. The development of this infection, in addition to the decline in

CD4 T cells and the increase in plasma HIV RNA concentrations, may signal antiretroviral failure. W.O.'s current antiretroviral therapy should be reassessed, including his adherence to the regimen.

Prophylaxis

CASE 77-2, QUESTION 3: Should W.O. have been receiving prophylactic therapy for T. gondii?

Similar to many other OIs associated with HIV, therapy for toxoplasmosis can be categorized into primary prophylaxis, treatment of acute disease, and secondary prophylaxis. Primary prophylaxis is currently recommended for HIV-infected patients with CD4 counts of less than 100 who are also IgG-positive for T. gondii (Table 77-2). Many of the agents used to prevent PCP have activity against T. gondii: TMP-SMX, dapsone–pyrimethamine–leucovorin, and atovaquone with or without pyrimethamine/leucovorin are effective as primary prophylaxis for T. gondii.[12] The increased use of prophylaxis with these agents has significantly decreased the incidence of Toxoplasma encephalitis.[2],[12] The double-strength TMP-SMX tablet once daily is recommended as the first-line prophylaxis. Data do not support the use of macrolides

---

or aerosolized pentamidine for Toxoplasma prophylaxis. Similarly, data are conflicting regarding the efficacy of pyrimethamine as monotherapy for primary prophylaxis.[62],[63]

Primary prophylaxis may be discontinued in patients who have responded to HAART with an increase in the CD4 counts to greater than 200 for more than 3 months. In addition, data support reinstituting primary prophylaxis when CD4 counts drop below 200.

W.O. is currently receiving inhaled pentamidine for PCP prophylaxis. Considering his CD4 count and IgG seropositivity, he should have received primary prophylaxis for T. gondii.

Treatment

ACUTE THERAPY

CASE 77-2, QUESTION 4: How should W.O.'s presumptive Toxoplasma encephalitis be treated?

The first-line treatment of acute Toxoplasma encephalitis consists of a combination of sulfadiazine 4 g/day in three or four daily divided doses and pyrimethamine as a single 200-mg loading dose, followed by 50 to 75 mg/day as a single daily dose plus leucovorin 10 to 25 mg PO every day.[12] Induction therapy should be continued for 6 weeks after resolution of symptoms (a treatment course of approximately 8 weeks) followed by maintenance therapy (secondary prophylaxis). Sulfadiazine toxicity may limit the completion of a full course of therapy in as many as 40% of patients.[64] However, successful desensitization has been documented.[65] W.O.'s clinical and radiologic response should be monitored closely, and other diagnoses should be considered if there is no improvement.

Alternative therapy includes pyrimethamine plus leucovorin with clindamycin 600 to 900 mg IV every 6 hours or 600 mg PO every 6 hours for at least 6 weeks. One controlled trial compared the efficacy and tolerability of pyrimethamine plus sulfadiazine versus pyrimethamine plus clindamycin. Although both regimens were effective, pyrimethamine–sulfadiazine was superior to pyrimethamine–clindamycin. The rate of adverse events was similar with both regimens; however, pyrimethamine–clindamycin led to fewer discontinuations than pyrimethamine–sulfadiazine (11% vs. 30%, respectively).[66] TMP-SMX may be considered a treatment option, particularly in patients who cannot take an oral regimen because the only widely available parenteral sulfonamide is the sulfamethoxazole component of TMP-SMX. However, there is less in vitro activity and less clinical data to support the use of TMP-SMX as monotherapy for toxoplasmosis.[67] Additionally, anticonvulsants should be given to patients with Toxoplasma encephalitis and a history of seizures, and corticosteroids may be warranted for focal lesions or edema but should be used cautiously.

CASE 77-2, QUESTION 5: W.O. is treated with sulfadiazine–pyrimethamine. What are the limitations to the use of the sulfadiazine component for the treatment of Toxoplasma encephalitis?

As with other sulfonamides in HIV-infected patients, rashes commonly occur with sulfadiazine therapy.[64] Similar to TMP-SMX, various desensitization regimens have been recommended[40],[65]; however, it may be simpler to use alternative regimens.

Renal function should be monitored throughout therapy. Elevated serum creatinine (SCr) levels, hematuria, or decreased urine output may occur secondary to sulfadiazine-induced crystalluria. The water solubility of sulfadiazine is less than that of other sulfonamides; therefore, hydration (2–3 L/day) is needed to prevent crystalline nephropathy, and aggressive hydration and alkalinization can be used in cases of crystal formation.

CASE 77-2, QUESTION 6: What toxicities are associated with the pyrimethamine component?

Pyrimethamine can suppress bone marrow function; thus, concomitant therapy with other medications that suppress marrow function (e.g., zidovudine [AZT] or ganciclovir) may not be tolerated. Leucovorin (10–25 mg/day) is always given in conjunction with pyrimethamine to maintain bone marrow function, although it may not always be successful. Leucovorin doses can be increased to 50 to 100 mg/day in divided doses if needed to reverse bone marrow suppression.[12] Folic acid (not folinic acid) should be avoided because it can be used for growth by protozoal organisms, potentially antagonizing pyrimethamine–sulfadiazine activity.[68] Vitamin preparations containing large quantities of folic acid should be discontinued during therapy for T. gondii.

W.O. is not taking any medications that would make him particularly susceptible to the myelosuppressive effects of pyrimethamine, and he is not neutropenic. Consequently, he should be given sulfadiazine and pyrimethamine.

SUPPRESSIVE THERAPY (SECONDARY PROPHYLAXIS)

CASE 77-2, QUESTION 7: Once W.O. has completed acute therapy for his Toxoplasma encephalitis, should he receive suppressive therapy?

Most antiprotozoal agents do not eradicate the cyst form of T. gondii. Therefore, patients should be administered lifelong suppressive therapy unless immune reconstitution occurs as a consequence of HAART.[12] A commonly used regimen for patients who cannot tolerate sulfonamides is pyrimethamine plus clindamycin. However, only the combination of pyrimethamine plus sulfadiazine provides protection against PCP as well. Additionally, two small studies of patients receiving maintenance therapy for Toxoplasma encephalitis have suggested that sulfadiazine–pyrimethamine is more effective than clindamycin–pyrimethamine or pyrimethamine alone.[66] The use of atovaquone with or without pyrimethamine is also effective as prophylaxis for both Toxoplasma and PCP, but it is significantly more expensive and is only available as a less palatable liquid formulation.

Patients receiving secondary prophylaxis are at a low risk for recurrence of Toxoplasma encephalitis when they have completed their initial therapy, remain asymptomatic, and have a sustained increase in their CD4 count to greater than 200 after more than 6 months of HAART. Clinicians may obtain a brain MRI as part of the evaluation to determine the end point of therapy. Discontinuation of primary and secondary toxoplasmosis prophylaxis is safe if patients are receiving HAART and their CD4 count has increased to greater than 200 for at least 3 months. Secondary prophylaxis should be reintroduced if the CD4 count decreases to less than 200.[12]

W.O. will be continued on sulfadiazine–pyrimethamine for suppressive therapy for his Toxoplasma encephalitis because his CD4 count has decreased to less than 100. W.O. is currently receiving aerosolized pentamidine for PCP prophylaxis, but because sulfadiazine–pyrimethamine is also protective against PCP, the aerosolized pentamidine can be discontinued. Clindamycin–pyrimethamine is an inferior option because it does not protect against PCP.[12]

ALTERNATIVE THERAPIES

CASE 77-2, QUESTION 8: What treatment options exist for patients who cannot tolerate sulfadiazine and do not wish to undergo desensitization?

Clindamycin 1,200 mg IV or PO every 6 hours or 600 mg PO every 6 hours plus pyrimethamine and leucovorin at standard doses.[12] Combination therapy with pyrimethamine and leucovorin plus azithromycin (1.2–1.5 g/day), clarithromycin (1 g BID), or atovaquone (750 mg PO 4 times a day) has shown promise in a limited numbers of patients.[12]

CYTOMEGALOVIRUS DISEASE

Diagnosis

CASE 77-3

QUESTION 1: P.Z., a 39-year-old man with AIDS, complains of floating spots, light flashes, and difficulty reading road signs when he drives. His most recent laboratory results were as follows:

BUN, 17 mg/dL
SCr, 0.8 mg/dL
CD4 count, 40 cells/μL
Viral load, 80,000 copies/mL (3 months ago)
WBC count, 1,200 cells/L, with 63% polymorphonuclear neutrophil leukocytes

His current weight is 63 kg. P.Z.'s medications include tenofovir, emtricitabine, atazanavir, ritonavir, dapsone (PCP prophylaxis), and azithromycin (MAC prophylaxis). He has a history of hematologic intolerance to AZT and TMP-SMX. P.Z. is known to have a positive CMV IgG antibody titer. Funduscopic examination reveals alternating areas of hemorrhage and scar tissue (a "cottage cheese and ketchup" appearance) in the proximity of the retina in his left eye.

What is the likely cause of P.Z.'s visual problems?

P.Z. has an inflammation of the retina (retinitis), most likely because of CMV. Many HIV-infected patients have been previously infected with CMV, and reactivation typically occurs when CD4 counts are less than 50. Before HAART, the prevalence of CMV disease in patients with AIDS was 30%; however, the incidence of new cases of CMV end-organ disease has declined by 75% to 80% since the advent of HAART and is estimated to be less than 6 cases per 100 person-years.[12],[69] Although CMV can cause colitis, pneumonitis, esophagitis, hepatitis, and neurologic disease, retinitis is the most common manifestation of active infection in AIDS patients, accounting for 75% to 85% of CMV end-organ disease. One investigation describing patients with CMV retinitis in the post-HAART era found a diverse demographic group with infection; most of them had received HAART, and as expected, they had very low CD4 counts.[70] In addition, the characteristics of the disease in this group were similar to those in the pre-HAART era. Diagnosis is usually presumptive because biopsy is difficult given the inaccessibility of the retina. Serology is indicative of previous CMV infection, but not an active disease. Cultures (serum, urine, and saliva) may be useful for monitoring therapy, considering that patients frequently have disseminated CMV disease. Patients with positive cultures for CMV while receiving therapy may be at a higher risk for relapse.[71] Typically, the diagnosis of CMV retinitis is based on observations made during a dilated retinal examination and indirect ophthalmoscopy, as was done for P.Z. Lesions appear as fluffy, white retinal patches with retinal hemorrhage.

Once CMV retinitis is diagnosed, the patient should be thoroughly examined for extraocular CMV disease. P.Z. will require regular ophthalmologic examinations, along with retinal photographs, for life. As with HIV therapy, CMV deoxyribonucleic acid (DNA) quantification in plasma or blood cells by polymerase chain reaction may have a role in evaluating treatment efficacy and predicting symptomatic development of CMV disease.[12]

Drug Therapy

CASE 77-3, QUESTION 2: What are the treatment options for CMV retinitis, and which one would be preferred for P.Z.?

Several treatment options exist for CMV retinitis: oral valganciclovir, IV ganciclovir, IV ganciclovir followed by oral valganciclovir, IV foscarnet, and IV cidofovir. Alternatives include combined IV ganciclovir plus foscarnet or intraocular injections of ganciclovir, foscarnet, or cidofovir.[12] The efficacy of combined parenteral ganciclovir and foscarnet is similar to that in monotherapy, but it is more toxic. This latter therapy should be reserved for patients with refractory disease (Table 77-3).[72]

Intraocular implants and intraocular injections of ganciclovir have similar efficacy in the treatment of CMV retinitis, but their benefit is localized to the infected eye and may lead to an increased risk of contralateral retinitis and extraocular CMV disease. Regimens consisting of systemic anti-CMV therapy have been associated with a 50% reduction in mortality compared with those using intraocular therapy alone.[73] Therefore, concomitant systemic anti-CMV therapy is recommended (e.g., oral valganciclovir or IV ganciclovir). The use of ganciclovir intraocular implants with oral valganciclovir has shown to be more effective at preventing relapse of retinitis than IV ganciclovir and likely oral valganciclovir.[12] Many providers prefer this as the first-line therapy in patients with immediate sight-threatening lesions, although others chose oral valganciclovir as the first-line treatment. The choice of agents typically depends on drug efficacy, toxicity, stage of disease, and quality-of-life issues.

GANCICLOVIR

Ganciclovir is an acyclic nucleoside with CMV activity superior to acyclovir. Similar to other nucleosides, ganciclovir must be taken into cells and phosphorylated before it can compete with endogenous nucleotides for binding to viral DNA polymerase. Ganciclovir is poorly absorbed PO (bioavailability, approximately 5%–9%), and the oral form is no longer marketed. The disposition of ganciclovir is biexponential after IV administration (terminal half-life, approximately 2.5 hours). The total body clearance is highly dependent on glomerular filtration and tubular secretion.

The dose-limiting toxicity is bone marrow suppression, with neutropenia occurring in approximately 50% of patients. Thrombocytopenia is also observed. Absolute neutrophil counts (ANCs) and platelets should be monitored weekly during ganciclovir therapy. If the ANC falls to less than 1,000 cells/ µL or the platelet count falls to less than 50,000/µL, the monitoring frequency should be increased to twice weekly.[27],[74] Ganciclovir is also available as an intraocular implant (Table 77-3). Dosage adjustments must be made in patients with renal dysfunction (Table 77-4).

Patients who develop ganciclovir-induced bone marrow suppression can be given granulocyte colony-stimulating factor (G-CSF). Both G-CSF (filgrastim) and granulocyte-macrophage colony-stimulating factor (GM-CSF [sargramostim])[75],[76] have been used successfully in stimulating production of WBC. Although neither of these agents is FDA-approved for this indication, the use of the CSFs may allow for continuation of sight-saving or life-prolonging therapy. Because GM-CSF may stimulate HIV replication in macrophage cell lines,[77] patients should receive concomitant antiretroviral therapy.

VALGANCICLOVIR

Valganciclovir is an oral monovalyl ester prodrug that is rapidly hydrolyzed to ganciclovir. The absolute bioavailability of ganciclovir from valganciclovir is 60%, and a dose of 900 mg results in ganciclovir blood concentrations similar to those obtained with a dose of 5 mg/kg of IV ganciclovir. Oral valganciclovir and IV ganciclovir are equally effective as induction therapy for newly diagnosed CMV retinitis in patients with AIDS.[78] The frequency and severity of adverse events were similar in the two groups. Based on these data, oral valganciclovir is as effective as and no more toxic than IV ganciclovir, and the convenience of the oral route suggests it be the drug of choice for the long-term management of CMV retinitis in patients with AIDS.

Table 77-3

Treatment of Cytomegalovirus Retinitis

	IV Ganciclovir	Valganciclovir	IV Foscarnet	Combination IV Ganciclovir and IV Foscarnet Sodium	IV Cidofovir
Dosing regimens	Induction: 5 mg/kg every 12 hours for 14–21 days	Induction: 900 mg every 12 hours for 14–21 days	Induction: 90 mg/kg every 12 hours for 14–21 days	Prior ganciclovir induction: both IV foscarnet 90 mg/kg every 12 hours and IV ganciclovir 5 mg/kg daily for 14–21 days	Induction: 5 mg/kg every week for 2 weeks
	Maintenance: 5 mg/kg daily	Maintenance: 900 mg daily	Maintenance: 90–120 mg/kg daily; 750–1,000 mL of 0.9% saline or D_5W solution with each dose	Maintenance: both IV foscarnet 90–120 mg/kg and IV ganciclovir 5 mg/kg daily	
	Refractory disease induction: 7.5 mg/kg every 12 hours for 14–21 days	Alternative regimen: with ganciclovir intraocular implant 900 mg daily		Prior foscarnet sodium induction: both IV ganciclovir 5 mg/kg every 12 hours and IV foscarnet 90–120 mg/kg daily	
	Maintenance: 10 mg/kg daily (Note: dosage should be adjusted for creatinine clearance <70 mL/minute; see Table 77-4)			Reinduction: IV ganciclovir 5 mg/kg and IV foscarnet 90 mg/kg every 12 hours for 14–21 days	
Select adverse effects	Neutropenia, thrombocytopenia, and catheter sepsis	Same as ganciclovir	Nephrotoxicity, electrolyte abnormalities, anemia, catheter sepsis, nausea/irritability, and genital ulceration	Same as IV ganciclovir and IV foscarnet	Nephrotoxicity, neutropenia, probenecid adverse effects (rash, fever, nausea, and fatigue), uveitis, alopecia, and hypotonia
Important drug interactions	Neutropenia, with AZT, cancer chemotherapy didanosine levels	Same as ganciclovir	Nephrotoxicity with other nephrotoxic drugs (e.g., amphotericin B,	Same as IV ganciclovir and IV foscarnet	Nephrotoxicity with other nephrotoxic drugs (e.g.,

			aminoglycosides, and IV pentamidine)		amphotericin B, aminoglycosides, IV pentamidine, and NSAIDs)
					Probenecid: Level of most proximal tubular excreted drugs
Adjunctive therapy	G-CSF/GM-CSF effective for neutropenia	Same as ganciclovir	IV or oral hydration essential; potassium, calcium/magnesium supplements, and antiemetics may be required	Same as both IV ganciclovir and IV foscarnet	Probenecid and IV hydration essential; antiemetics, antihistamine, and acetaminophen premedication commonly used for probenecid toxicity
Advantages	Systemic therapy; anti-HSV activity	Increased bioavailability and decreased pill count compared with PO ganciclovir	Systemic therapy; anti-HSV (acyclovir-resistant) activity; anti-HIV activity	Increased efficacy compared with either IV ganciclovir or IV foscarnet alone; improved response for relapsed disease	Systemic therapy; no indwelling catheter required; infrequent dosing
Disadvantages	Hematologic toxicity; requires daily infusions; and indwelling catheter	Must have adequate GI absorption; less clinical data than with ganciclovir	Nephrotoxicity; requires daily infusions/indwelling catheter; supplemental hydration required; prolonged infusion time; and requires infusion pump or controlled rate infusion device	Same as IV ganciclovir and IV foscarnet; prolonged daily infusion time and impact on quality of life	Requires probenecid and IV hydration; probenecid toxicity; and nephrotoxicity (may be prolonged)

Monitoring requirement	Induction therapy: (a) CBC with WBC differential, platelet count weekly; (b) SCr weekly	Same as ganciclovir	Induction therapy: (a) SCr twice weekly; (b) serum Ca^{2}+, albumin Mg^{2}+, phosphates, and K+ twice	Same as both IV ganciclovir and IV foscarnet	Within 48 hours before each induction and maintenance: (a) SCr quantitation proteinuria; and

			weekly; and (c) Hgb and Hct weekly		(b) WBC with differential cell count; monitor intraocular pressure and slit-lamp examination at least monthly
	Maintenance therapy: (a) CBC with WBC differential, platelet count weekly; and (b) SCr every 24 weeks		Maintenance therapy: (a) SCr weekly; (b) serum Ca^{2}+, albumin Mg^{2}+, phosphates, and K+ weekly; and (c) Hgb and Hct every 24 weeks		
Precautions and contraindications	Moderate-to-severe thrombocytopenia (platelet counts $<25 \times 10^{10}$/L)	Same as ganciclovir	Concomitant use with other nephrotoxic drugs (e.g., amphotericin B, aminoglycosides, or IV pentamidine) or in patients with preexisting moderate-to-severe renal insufficiency (SCr >168 mmol/L or creatinine clearance <50 mL/minute)	Same as both IV ganciclovir and IV foscarnet	Same as IV foscarnet except parameters are baseline SCr level (>1.5 mg/dL) or creatinine clearance (<55 mL/minute), or 2+ proteinuria (after IV fluid); discontinue therapy for 3+ proteinuria, if SCr level increases by 0.5 mg/dL above baseline, or intraocular pressure decreases by 50% of baseline value

AZT, zidovudine; CBC, complete blood count; CMV, cytomegalovirus; G-CSF, granulocyte colony-stimulating factor; D_5W, 5% dextrose in water solution; GI, gastrointestinal; GM-CSF, granulocyte-macrophage colony-stimulating factor; Hct, hematocrit; Hgb, hemoglobin; HIV, human immunodeficiency virus; HSV, herpes simplex virus; IV, intravenously; NSAIDs, nonsteroidal anti-inflammatory drugs; PO, orally; SCr, serum creatinine; WBC, white blood cells.

CIDOFOVIR

Cidofovir is a nucleotide analog that is phosphorylated intracellularly to an active diphosphate metabolite. It is the most potent of all the available anti-CMV compounds and is active against herpes simplex virus (HSV) and VZV, including acyclovir-resistant isolates. Cidofovir does not require viral activation. Because nucleotide analogs do not require virally encoded kinases for their activity, they remain a treatment option for patients who have failed to respond to ganciclovir. Cidofovir is poorly absorbed PO (bioavailability, <5%) and has an intracellular half-life of 17 to 65 hours, resulting in once-weekly induction and every-other-week maintenance therapy.

Eighty percent of this poorly soluble agent is excreted unchanged in the urine via filtration and tubular secretion. Cidofovir is nephrotoxic; however, the administration of probenecid (2 g administered 3 hours before the start of infusion and two 1-g doses administered at 2 and 8 hours after infusion) blocks tubular secretion and reduces nephrotoxicity. Prehydration with 1 L of normal saline is required 1 hour before each dose and, if tolerated, repeated concomitantly with or after the cidofovir infusion. Because nephrotoxicity is the most significant dose-limiting toxicity, other nephrotoxic agents should be discontinued (e.g., nonsteroidal anti-inflammatory drugs, and aminoglycosides), and renal function should be carefully monitored throughout therapy (BUN, SCr, and proteinuria; Table 77-4). Dosage adjustment must accompany any deterioration in renal function (Table 77-5).

The CBC should be checked at baseline because neutropenia has been reported in approximately 20% of patients in clinical trials. Hypotony (reduction in intraocular pressure) and uveitis (inflammation of the uveal tract of the eye) have also been reported. Thus, monthly ophthalmologic examinations of the retina are necessary.[12]

The role of cidofovir is limited. Although it offers the advantage of weekly and biweekly dosing, its toxicity greatly limits its utility. Cidofovir appears to be as efficacious as foscarnet and ganciclovir in the treatment of CMV retinitis, but limited comparative studies have been performed. Finally, the efficacy of cidofovir in the treatment of extraocular CMV (e.g., GI disease, pneumonitis, and encephalitis) remains to be established.

Table 77-4

Dosage Adjustment for Cytomegalovirus Medications

Drug	Normal Dosage	CrCl (mL/minute/1.73 m^2)	Adjusted Dosage			

Cidofovir	Induction dose: 5 mg/kg IV QW × 2 doses	Increase in SCr of 0.3–0.4 above baseline	3 mg/kg per dose			
	Maintenance dose: 5 mg/kg IV QOW	Increase in SCr of 0.5 above baseline or 3+ proteinuria	Discontinue cidofovir			
		Cidofovir is contraindicated in patients with preexisting renal failure: 1. SCr concentrations >1.5 mg/dL 2. Calculated CrCl of <55 mL/minute 3. Urine protein 100 mg/dL (>2+ proteinuria)				
			Induction Dose		Maintenance Dose	
Foscarnet	Induction dose:	CrCl (mL/minute/kg)	Low Dose	High Dose	Low Dose	High Dose
	IV every 8 hours to 90 mg/kg	>1.4	60 mg/kg every 8 hours	90 mg/kg every 12 hours	90 mg/kg every 24 hours	120 mg/kg every 24 hours
	IV every 12 hours	1.0–1.4	45 mg/kg every 8 hours	70 mg/kg every 12 hours	70 mg/kg every 24 hours	90 mg/kg every 24 hours
	Maintenance dose: 90–120 mg/kg IV daily	0.8–1.0	50 mg/kg every 12 hours	50 mg/kg every 12 hours	50 mg/kg every 24 hours	65 mg/kg every 24 hours
		0.6–0.8	40 mg/kg every 12 hours	80 mg/kg every 24 hours	80 mg/kg every 48 hours	105 mg/kg every 48 hours
		0.5–0.6	60 mg/kg every 24 hours	60 mg/kg every 24 hours	60 mg/kg every 48 hours	80 mg/kg every 48 hours
		0.4–0.5	50 mg/kg every 24 hours	50 mg/kg every 24 hours	50 mg/kg every 48 hours	65 mg/kg every 48 hours
		<0.4	Not recommended		Not recommended	

Ganciclovir			Maintenance dose			
	IV					
	Induction	CrCl (mL/minute)	Induction		Maintenance	

	dose: 5 mg/kg every 12 hours		dose		dose	
		>70	5 mg/kg every 12 hours		5 mg/kg every 24 hours	
	Maintenance dose: 5 mg/kg daily or 6 mg/kg daily × 5 day/week	50–69	2.5 mg/kg every 12 hours		2.5 mg/kg every 24 hours	
		25–49	2.5 mg/kg every 24 hours		1.25 mg/kg every 24 hours	
		10–24	1.25 mg/kg every 24 hours		0.625 mg/kg every 24 hours	
		<10	1.25 mg/kg 3 × every week after hemodialysis		0.625 mg/kg 3 × every week after hemodialysis	
Valganciclovir	Induction dose: 900 mg PO BID	CrCl (mL/minute)	Induction dose		Maintenance dose	
	Maintenance dose: 900 mg PO daily	40–59	450 mg BID		450 mg daily	
		25–39	450 mg daily		450 mg every other day	
		10–25	450 mg every other day		450 mg BIW	
		Hemodialysis	Not recommended		Not recommended	

BID, twice a day; BIW, twice a week; CrCl, creatinine clearance; IV, intravenously; PO, orally; QOW, every other week; QW, weekly; SCr, serum creatinine; TID, three times a day; TIW, three times a week.

FOSCARNET

Foscarnet is a pyrophosphate analog that acts by selectively inhibiting viral DNA polymerases and reverse transcriptase. At doses currently recommended for induction therapy (60 mg/kg every 8 hours or 90 mg/kg IV every 12 hours), peak plasma foscarnet concentrations are higher than those that inhibit CMV in vitro (Table 77-4).[79] The dose-limiting toxicity of foscarnet is nephrotoxicity, probably because its poor solubility results in crystallization in nephrons.[74] In one trial, when compared with ganciclovir, patients treated with foscarnet survived approximately 4 months longer; however, foscarnet-treated patients with reduced creatinine clearance (<1.2 mL/minute/kg) had a poorer survival rate.[80]

Because P.Z. has a low ANC, the bone marrow–suppressive effects of ganciclovir and valganciclovir are of concern. Adjunctive therapy with G-CSF is an option. Because he has good renal function (SCr, 0.8 mg/dL), foscarnet or cidofovir would be an option.

Nephrotoxicity

CASE 77-3, QUESTION 3: P.Z. will receive foscarnet, 90 mg/kg IV for 2 hours every 12 hours. How can the risk of nephrotoxicity be minimized?

During foscarnet therapy, adequate hydration is important to prevent nephrotoxicity. To establish diuresis, 750 to 1,000 mL of normal saline or 5% dextrose should be administered before the first infusion of foscarnet. With subsequent infusions, 500 to 1,000 mL should be administered, depending on the foscarnet dose. Careful dosage titration based on P.Z.'s estimated creatinine clearance may also minimize nephrotoxicity (Table 77-5). The SCr clearance should be measured at least twice weekly and the dosage should be recalculated if the creatinine clearance changes. CMV infection itself may also cause an acute increase in the SCr owing to acute interstitial nephritis. Drugs with nephrotoxic potential, such as amphotericin B or aminoglycosides, should be avoided.

Adverse Effects

CASE 77-3, QUESTION 4: What toxicities other than nephrotoxicity have been associated with foscarnet therapy?

Hypocalcemia can occur because foscarnet, a pyrophosphate analog, can bind to unbound calcium. Electrolyte complications can be minimized by avoiding high foscarnet plasma concentrations with slow infusions over 1 to 2 hours.[81] Unbound serum calcium and phosphate levels should be monitored twice weekly during induction therapy and weekly during maintenance therapy, ideally when foscarnet is at its highest concentration. Fatal hypocalcemia has been reported in an AIDS patient receiving both foscarnet and parenteral pentamidine; thus, coadministration of these drugs should be avoided.[82]

Penile ulceration from foscarnet has been problematic, especially in uncircumcised men. Characterized as a fixed drug eruption, careful attention to genital hygiene may minimize the potential for penile ulceration. Other adverse events associated with foscarnet include seizures, hypomagnesemia, anemia, nausea, fever, and rash. Twice-weekly albumin, magnesium, and potassium levels are required during induction therapy and then weekly during maintenance therapy. In general, patients tolerate foscarnet less well than ganciclovir.[80]

Dosage Adjustments

CASE 77-3, QUESTION 5: After 12 days of foscarnet therapy, P.Z.'s SCr has increased from 0.8 to 1.2 mg/dL despite the coadministration of 2 L of normal saline daily. What dosage adjustments should be made for the remainder of the foscarnet treatment?

Valganciclovir, ganciclovir, foscarnet, and cidofovir are highly dependent on renal elimination, and dosages (or dosing intervals) should be adjusted for even a modest reduction in renal function (Table 77-5). Therefore, careful monitoring of renal function is important throughout CMV therapy. P.Z.'s estimated creatinine clearance is 1.2 mL/minute/kg; therefore, his foscarnet induction dosage should be adjusted to 70 mg/kg IV every 12 hours (Table 77-5).[12]

Suppression Therapy

CASE 77-3, QUESTION 6: P.Z. completes 21 days of foscarnet induction therapy. How can his CMV retinitis be suppressed in the future?

The currently available antiviral agents used to treat CMV disease are not curative. After induction therapy, chronic maintenance therapy is indicated for the remainder of P.Z.'s life, unless immune reconstitution occurs as a result of HAART. Effective suppressive regimens include parenteral or oral ganciclovir, parenteral foscarnet, combined parenteral ganciclovir and foscarnet, and parenteral cidofovir. The ganciclovir implant was also effective but is no longer manufactured (Table 77-4). Oral valganciclovir is approved for both acute induction and maintenance therapy, but the published clinical data are limited. In uncontrolled case series, repeated intravitreal injections of ganciclovir, foscarnet, and cidofovir have been shown to be effective for prophylaxis of CMV retinitis. However, because this therapy is effective only

---

locally and does not protect the contralateral eye or other organ systems, it is usually combined with oral valganciclovir.

Guidelines suggest that discontinuation of prophylaxis may be considered in patients with CMV retinitis who are taking HAART with a sustained (>6 months) increase in the CD4 count to greater than 100 to 150 and have remained disease-free for more than 30 weeks. The decision to discontinue suppression should be based on the magnitude and duration of the CD4 increase and viral load suppression, the anatomic location of the retinal lesions, and the degree of vision loss.[12] All patients who have had anti-CMV maintenance therapy discontinued should continue to undergo regular ophthalmologic monitoring for early detection of CMV relapse as well as for immune reconstitution uveitis.

Relapse or Refractory Cytomegalovirus Retinitis

CASE 77-3, QUESTION 7: After 5 months of maintenance therapy with foscarnet, a routine funduscopic examination reveals retinal CMV disease progression. How should P.Z.'s retinitis be managed at this time?

Most patients with CMV not receiving HAART while undergoing maintenance treatment eventually relapse.[12] For the first relapse, repeat induction therapy followed by maintenance therapy with the same drug is beneficial in most patients. Because P.Z. has tolerated foscarnet therapy thus far, he should receive another course of induction therapy. After reinduction, P.Z. should receive a higher maintenance dosage (120 mg/kg/day).[12]

It is important to distinguish between relapse and refractory disease. Relapse, as in the case of P.Z., is defined as the recurrence of clinically apparent viral activity and is usually caused by a decline in immune function, insufficient delivery of drug into the eye, or resistant CMV strains. Relapse can effectively be managed by repeat induction therapy of the same drug. If the relapse is caused by a resistant virus, the patient may benefit from a change in therapy. Ganciclovir-resistant CMV strains occur by two mechanisms. DNA polymerase mutation at the UL54 gene is observed in approximately 20% of ganciclovir-resistant strains. This mutation usually confers resistance to cidofovir and, to a lesser extent, foscarnet.[12] Most ganciclovir-resistant CMV strains have UL97 mutations. UL97 mutations are incapable of monophosphorylating ganciclovir. Cidofovir and foscarnet are appropriate alternatives to treat strains with UL97 mutations. Patients who receive extensive ganciclovir treatment (>6–9 months) may present with highly ganciclovir-resistant strains containing UL54 and UL97 mutations.[83] Cidofovir may be considered in most patients who relapse while receiving ganciclovir or foscarnet. Although ganciclovir-resistant and foscarnet-resistant strains of CMV have been reported, their precise role in the clinical failure of these regimens is not known. Because of the different mechanisms of action of ganciclovir and foscarnet, strains resistant to one drug may retain sensitivity to the other.[84] Resistant or relapsing CMV retinitis may be treated by the administration of local ocular therapy via intravitreal injection of ganciclovir or foscarnet (see Local Treatment section).

Refractory CMV retinitis is defined by disease progression because of ineffective therapy. This phenomenon is observed in two clinical situations: when the disease persists with minimal or no response during induction therapy and when long-term control is inadequate with maintenance therapy. Refractory CMV disease has been defined in clinical trials as two relapses occurring within 10 weeks despite repeat induction and maintenance therapy. Treatment options for refractory CMV retinitis include reinduction with ganciclovir at higher dosages (7.5 mg/kg/dose every 12 hours, followed by maintenance doses of 10 mg/kg/day) or reinduction using combination therapy (IV ganciclovir plus foscarnet).[27] Refractory CMV retinitis can be treated with local ocular therapy via intravitreal injection of ganciclovir or foscarnet.[12]

Local Treatment

CASE 77-3, QUESTION 8: What is the role of intravitreal injections in CMV retinitis?

INTRAVITREAL INJECTIONS

Intravitreal administration of ganciclovir or foscarnet through a small-gauge needle is a method of selectively delivering the drug to the site of infection. Ganciclovir and foscarnet doses of 0.2 to 2 mg and 1.2 to 2 mg, respectively, are administered 2 or 3 times per week for active disease, followed by weekly maintenance injections.[27] Potential complications of intravitreal injections include bacterial endophthalmitis, vitreous hemorrhage, and retinal detachment. Intravitreal therapy is relatively uncommon because intraocular implants are available. Importantly, in contrast to systemic therapy, local instillation of a drug is associated with a higher risk of CMV disease developing in the contralateral eye as well as extraocular sites (Table 77-3).

Intraocular Ganciclovir Implants

CASE 77-3, QUESTION 9: Is P.Z. a candidate for ganciclovir intraocular implants?

The ganciclovir implant (no longer manufactured) was a surgically implanted reservoir of ganciclovir very effective in less severe vision loss, but ocular complications including cataract, vitreous hemorrhage, and retinal detachment were common.[85]

P.Z. should be reinduced with foscarnet therapy and maintained on a higher foscarnet dose. Neither alternating regimens nor intravitreal administration of antiviral agents is appropriate at present.

Valganciclovir

CASE 77-3, QUESTION 10: What is the role of valganciclovir for initial CMV prevention?

Valganciclovir has replaced oral ganciclovir, which is no longer marketed. This agent yields an area under the curve approximately equivalent to that associated with the IV administration of ganciclovir. The maintenance dosage is two 450-mg tablets of valganciclovir once daily.

Data from clinical trials conducted with oral ganciclovir have been extrapolated to valganciclovir, and all references in the OI treatment guidelines to oral ganciclovir have been substituted with valganciclovir. The role of oral ganciclovir for primary prophylaxis of CMV retinitis has been evaluated in two studies.[86],[87] Oral ganciclovir decreased the 1-year incidence of disease by approximately 50% in one study[87] but was ineffective in another.[86] These two studies had important differences in study design that likely explains the disparate results. One cost-effectiveness study estimated that oral ganciclovir prophylaxis would cost more than $1.7 million per year of anticipated life expectancy.[88] Valganciclovir has not demonstrated a survival advantage in patients with CD4 count less than 50 using it for CMV primary prevention.[12] These issues, in addition to adverse effects such as neutropenia and anemia, the lack of proven survival benefit in HIV-infected patients, and the risk for inducing CMV resistance, are concerns that should be addressed when deciding whether to institute prophylaxis in

---

individual patients. Prophylaxis with valganciclovir is not recommended as the standard of care (Table 77-2).[12]

CRYPTOCOCCOSIS

Clinical Presentation and Prognosis

CASE 77-4

QUESTION 1: A.S., aged 28, is infected with HIV. She weighs 48 kg. Her boyfriend was an IV drug user who died of AIDS 2 years ago. She presents with a fever (103°F) and a 2-week history of "splitting headaches." Laboratory test results include the following:

Hemoglobin, 11.2 g/dL
WBC count, 4,100 cells/μL
Platelets, 73,000/L
SCr, 0.9 mg/dL
Glucose, 94 mg/dL
CD4 count, 47 cells/μL

A.S. is highly nonadherent and has not been to the clinic in more than a year, at which time she was prescribed tenofovir, emtricitabine, atazanavir, and ritonavir. Physical examination reveals no nuchal rigidity. With the exception of moderate lethargy, her neurologic examination is unremarkable. Her chest radiograph and three sets of blood cultures for bacteria and fungi are negative. A computed tomography scan is nondiagnostic. Lumbar puncture reveals the following CSF findings:

Glucose, 45 mg/dL
Protein, 90 mg/dL
WBC count, 10 cells/μL
Cryptococcal antigen titer, 1:2,048 IU
Intracranial pressure (ICP), 24 cm H_2O (normal, 8–22 cm H_2O)

How is A.S.'s clinical presentation typical of a patient with AIDS and cryptococcal meningitis? What is her likely prognosis?

In the pre-HAART era, cryptococcosis developed in approximately 6% to 10% of AIDS patients in the United States, with meningitis being the most common clinical presentation.[89] In the era of HAART and azole prophylaxis, a significant decline in the incidence of cryptococcosis has been observed.[89] Based on a 2010 cohort study, cryptococcosis is the second most common CNS infection associated with AIDS.[2] The initial portal of entry is the lungs, where the organism is normally contained by an intact immune system. Cryptococcal disease typically develops in patients with profound defects in cell-mediated immunity (i.e., CD4 counts, <50). Unlike bacterial meningitis, cryptococcal CNS infection has a much more insidious onset; the most common symptoms are fever and headache. Less frequent signs and symptoms include nausea and vomiting, meningismus, photophobia, and altered mental status. Focal neurologic deficits and seizures are observed in less than 10% of patients. CSF glucose is decreased, whereas CSF proteins are usually elevated. CSF cryptococcal antigen titer and CSF culture are frequently positive. These findings, along with the clinical presentation, form the basis for the diagnosis. The overall outcome is poor, with a mean survival of 5 months in patients not receiving HAART. Relapse within 6 months occurs in 50% of patients who do not receive suppressive therapy. Altered mental status at baseline, CSF WBC count of less than 20 cells/ µL, high CSF cryptococcal antigen titer (>1:1,000), and an elevated initial CSF opening pressure of greater than 20 cm H_2O have all been associated with a poor prognosis.[89]

A.S.'s CD4 count is 92. She has a temperature of 103°F and has experienced "splitting headaches" for about a week. Her clinical presentation is typical of an AIDS patient with cryptococcal meningitis. The CSF WBC count of 10 cells/µL, high cryptococcal antigen titer, and ICP greater than 20 cm H_2O suggest a poor prognosis.[90] If left untreated, cryptococcal meningitis is fatal.

Treatment

AMPHOTERICIN B

CASE 77-4, QUESTION 2: How should A.S.'s acute cryptococcal meningitis be managed?

The current treatment recommended for cryptococcal meningitis is amphotericin B, 0.7 mg/kg/day IV, plus flucytosine (100 mg/kg/day) given PO in four divided doses as induction therapy for 14 days. Once the patient is stable (e.g., afebrile, with the resolution of symptoms), then consolidation therapy with oral fluconazole 400 mg/day for 8 weeks or until CSF cultures are sterile can be initiated. After consolidation therapy, daily suppressive therapy with fluconazole 200 mg should be continued indefinitely unless immune reconstitution occurs with HAART.[90] Lipid-based formulations of amphotericin B (specifically liposomal amphotericin, dosed as 4–6 mg/kg/day) are also effective.[91],[92]

Although the aforementioned regimen is highly effective, the ability to rapidly reduce A.S.'s ICP will also significantly improve her clinical course. Removal of 10 to 20 mL of spinal fluid by repeat lumbar puncture is recommended for patients with an ICP greater than 20 cm H_2O (A.S.'s ICP is 24 cm H_2O). An additional intervention to consider reducing A.S.'s elevated ICP is the insertion of an intraventricular shunt.[12]

CASE 77-4, QUESTION 3: What is the evidence for adding flucytosine to amphotericin B in the acute treatment of A.S.? What are the disadvantages of this combination?

Amphotericin B binds to sterols in the fungal cell membrane, resulting in leakage of cytoplasmic contents. Flucytosine is an antimetabolite type of antifungal drug that is activated by deamination within the fungal cells to 5-fluorouracil. It inhibits fungal protein synthesis by replacing uracil with 5-flurouracil in fungal RNA, and it also inhibits thymidylate synthase via 5-fluorodeoxy-uridine monophosphate, interfering with fungal DNA synthesis. Flucytosine, a purine analog, is approximately 10% converted to 5-fluorouracil, an antimetabolite, which is the mechanism for its potential bone marrow toxicity.

A classic prospective study conducted in HIV-negative patients favored the use of the combination.[93] The protocol randomly assigned patients to receive either amphotericin B monotherapy (0.4 mg/kg/day IV for 6 weeks followed by 0.8 mg/kg/day IV every other day for 4 weeks) or amphotericin B plus flucytosine (150 mg/kg/day PO divided every 6 hours) for 6 weeks. Fewer failures or relapses, more rapid CSF sterilization, and less nephrotoxicity occurred in the combination group, although overall mortality was not different. However, approximately one-fourth of the patients in the combination arm developed leukopenia, thrombocytopenia, or both.

If flucytosine is chosen as adjunctive therapy, renal function and CBCs should be monitored closely for these adverse effects. A.S. is at an increased risk of granulocytopenia because of her HIV infection and her concomitant myelotoxic AZT therapy.

The comparative trial forming the basis for the current recommendations for the treatment of acute cryptococcal meningitis in HIV-positive patients evaluated a higher dose of IV amphotericin B (0.7 mg/kg/day) with or without flucytosine given at a lower dose (25 mg/kg/dose PO every 6 hours) for 2 weeks.[90] The study evaluated 381 patients with an acute first episode of cryptococcal meningitis. The second part of this trial randomly reassigned stable or improved patients to either a fluconazole or an itraconazole treatment arm for an additional 8 weeks as consolidation therapy. Sixty percent and 51% of patients receiving amphotericin B plus flucytosine, and amphotericin B alone, respectively, had sterile CSF cultures at 2 weeks of therapy. No significant differences were noted between groups in the percentage of patients who were culture-negative at 2 weeks. Importantly, the addition of flucytosine to amphotericin B was not associated with a significant increase in drug toxicities at 2 weeks. Fluconazole and itraconazole were similar in efficacy. However, multivariate analysis revealed two factors that were independently associated with a higher rate of CSF sterilization: the addition of flucytosine and the randomization to fluconazole. A more recent trial randomized 299 patients to amphotericin B (1 mg/kg/day) for 4 weeks, amphotericin B (1 mg/kg/day) plus flucytosine (100 mg/kg/day divided) for 2 weeks, or amphotericin B (1 mg/kg/day) plus fluconazole (400 mg bid) for 2 weeks. Patients receiving amphotericin B and flucytosine had lower mortality rates and significantly increased rates of yeast clearance from CSF. Rates of adverse events were similar between groups with the exception of more frequent neutropenia in patients receiving a combination therapy. The addition of fluconazole provided no survival benefit.[94]

FLUCONAZOLE

CASE 77-4, QUESTION 4: Could A.S. be treated with fluconazole instead of amphotericin B for acute cryptococcal meningitis?

Fluconazole, one of the triazole antifungal agents, inhibits a fungal cytochrome P-450 enzyme necessary for the conversion of lanosterol to ergosterol. Without ergosterol, the fungal cell membrane becomes defective and loses its selective permeability properties. Unlike itraconazole, fluconazole is well absorbed PO even in the presence of an elevated gastric pH. Fluconazole has excellent CNS penetration and a good safety profile, but it is likely a secondary choice in the initial treatment of cryptococcal meningitis. In a prospective, randomized, multicenter trial, the National Institute of Allergy and Infectious Diseases Mycoses Study Group and the AIDS Clinical Trial Group compared amphotericin B with 200 mg/day of oral fluconazole (after a 400-mg loading dose) for 10 weeks in 194 patients.[95] The dose of amphotericin B (mean dose, 0.4–0.5 mg/kg/day) and the possible addition of flucytosine were left to the discretion of the individual investigators. Although the overall mortality was similar (14% for amphotericin B vs. 18% for fluconazole), more fluconazole-treated patients died during the first 2 weeks of treatment (15% vs. 8%; $p = 0.25$). Furthermore, the median time to the first negative CSF culture in the successfully treated patients was shorter in the amphotericin B group compared with fluconazole (16 vs. 30 days). In a small, prospective, randomized trial of 20 male patients with AIDS, oral fluconazole (400 mg/day) for 10 weeks was compared with IV amphotericin B (0.7 mg/kg/day for 1 week, followed by the same dose 3 times weekly for 9 weeks) combined with flucytosine (150 mg/kg/day).[96] There were four deaths in the fluconazole group and none in the amphotericin B group ($p = 0.27$). Eight of the 14 patients in the fluconazole group failed to respond to treatment, whereas none in the amphotericin B group failed to respond. The mean duration of positive CSF cultures was 41 days in the fluconazole group and 16 days in the amphotericin B group ($p = 0.02$). These results, taken together, have led most clinicians to choose amphotericin, with or without flucytosine, as initial treatment for severe cryptococcal meningitis. Although increased doses of fluconazole have been proposed, it is unknown whether these will result in improved outcomes. High doses of fluconazole are being investigated further for patients in the developing world where the use of IV amphotericin may not always be feasible. Considering the severity of her meningitis, A.S. should be treated acutely with amphotericin and not fluconazole.

DURATION OF THERAPY

CASE 77-4, QUESTION 5: How long should treatment continue for A.S.'s cryptococcal meningitis?

Once A.S. completes 2 weeks of acute induction therapy with amphotericin B and flucytosine, she should be switched, if stable, to oral fluconazole 400 mg/day for consolidation therapy. Consolidation should be continued for an additional 8 to 10 weeks, followed by lifelong suppressive therapy with fluconazole 200 mg/day[90] (see Maintenance Therapy section).

MAINTENANCE THERAPY

CASE 77-4, QUESTION 6: Should A.S. receive maintenance therapy after successful treatment?

After induction and consolidation treatment of cryptococcal meningitis, A.S. and all AIDS patients should receive maintenance therapy indefinitely, unless immune reconstitution occurs as a result of HAART.[12,89,90] A higher relapse rate and a shorter life expectancy have been observed in patients who did not receive chronic secondary prophylaxis.[97] Fluconazole (200 mg once daily) has emerged as the suppressive treatment of choice. In a randomized, placebo-controlled trial of 61 AIDS patients, four recurrent cases of meningitis developed in the placebo group and none in the fluconazole group.[98] A multicenter, comparative trial randomized patients to receive either weekly amphotericin B 1 mg/kg/day IV or 200 mg/day of fluconazole PO.[99] Of 189 patients enrolled, 18% of the patients in the amphotericin B group relapsed, compared with 2% in the fluconazole group. Serious toxicities were more frequent in the amphotericin B group.[90] The newer triazole antifungals, posaconazole and voriconazole, have limited experience as primary or maintenance therapy for patients with cryptococcosis and are associated with many drug interactions with antiretroviral therapy.[12]

According to the OI guidelines,[12] adult and adolescent patients are at a low risk for recurrence of cryptococcosis when they have completed a course of initial therapy, remain asymptomatic, and have a sustained increase (e.g., >6 months) in their CD4 counts to at least 200 after HAART. Thus, discontinuing chronic maintenance therapy among such patients is reasonable. Recurrences may occur, and some specialists recommend a repeat lumbar puncture to determine whether the CSF is culture-negative before stopping therapy. Maintenance therapy should be reinitiated if the CD4 count decreases to less than 200.

Primary Prophylaxis

CASE 77-4, QUESTION 7: What is the role of primary prophylaxis in cryptococcal meningitis?

Primary prophylaxis against cryptococcal disease in HIV-infected patients has been studied in a few clinical trials.[100,101] In an open-label study, fluconazole (100 mg/day) was administered to all patients (329 HIV-infected patients) with CD4 counts less than 68. These results were compared with 337 historical controls from the pre-HAART era.[100] Sixteen cases of cryptococcal meningitis occurred in the historical controls (4.8%) compared with only one case in the fluconazole group (0.3%). In a prospective, randomized AIDS Clinical Trial Group study, fluconazole 200 mg/day was compared with clotrimazole troches (10 mg 5 times a day) for

---

the prevention of fungal infections in 428 patients with advanced HIV disease. After a median follow-up of 35 months, 32 cases of invasive fungal infection were confirmed. Of these, the majority (17 of 32) were cryptococcosis: 2 cases in the fluconazole group and 15 cases in the clotrimazole group. The greatest benefit derived from fluconazole was observed in patients with CD4 counts of less than 50.[101] However, no effect on survival was noted. A randomized, double-blind, placebo-controlled trial of fluconazole 200 mg 3 times weekly versus placebo in Ugandan adults with CD4 counts less than 200 found fluconazole prophylaxis to be effective prophylaxis against cryptococcal disease, with 18 patients in the placebo group developing cryptococcal disease versus one patient in the fluconazole group. There was no difference in all-cause mortality between the groups.[100]

Fluconazole resistance has been reported in HIV-infected patients receiving a long-term therapy.[102] In addition to the potential for resistance, other concerns include the lack of survival benefits associated with prophylaxis, the possibility of drug interactions, and cost. In light of these concerns, the guidelines currently do not recommend primary prophylaxis for this disease (Table 77-1).[12]

ADDITIONAL THERAPIES

CASE 77-4, QUESTION 8: What other acute therapies have been investigated for cryptococcal meningitis?

High-dose fluconazole alone (800–2,000 mg/day for up to 6 months) has been compared with high-dose fluconazole and flucytosine (100–150 mg/kg/day for 4 weeks) in multiple clinical trials.[103–105] These studies have shown that the combination of fluconazole and flucytosine is superior to fluconazole alone in terms of both survival and CSF culture clearance. The combination of fluconazole and flucytosine is useful because of their excellent oral bioavailability, cost-effectiveness, and safety, which are particularly important in developing countries. Additionally, higher doses of fluconazole in these settings (1,800–2,000 mg/day) may be the best option for patients owing to the limitations of obtaining and administering flucytosine.

MYCOBACTERIUM TUBERCULOSIS

Clinical Presentation

CASE 77-5

QUESTION 1: C.J., a 45-year-old male prison inmate with AIDS, presents with fever, cough, and occasional night sweats. A tuberculin purified protein derivative (PPD) skin test is negative. Two acid-fast bacilli (AFB) sputum smears are also negative. Chest radiograph reveals hilar adenopathy with a questionable right middle lobe localized infiltrate. No cavitary lesions are seen. Why is infection with M. tuberculosis a strong possibility in C.J.? His antiretroviral medications include abacavir, lamivudine, and dolutegravir. Three months ago, his CD4 count was 120 cells/μL, and his viral load was 5,200 copies/mL.

TB is the second leading cause of mortality caused by infection worldwide—second only to HIV—with 9 million infections in 2013 and 1.5 million deaths.[106] Low- to middle-income countries account for 95% of deaths from M. tuberculosis. Of the cases in 2013, 480,000 patients developed multidrug-resistant TB. In the United States, 9,582 cases of TB occurred in 2013, which was a 3.6% decline in the number of cases when compared with 2012.[107] The recognized link between HIV and TB, along with an increase in clinical and public health resources, has subsequently resulted in a decline in the incidence of TB in the United States.[107]

C.J. presents with fever, cough, night sweats, and a right middle lobe infiltrate with hilar adenopathy, consistent with TB. Furthermore, his HIV status in combination with his incarceration increases the probability of M. tuberculosis infection, including multidrug-resistant isolates. C.J. will be started with the standard four-drug regimen: isoniazid, rifampin (or rifabutin), pyrazinamide, and ethambutol.[12] (See Chapter 68, Tuberculosis, for a more comprehensive approach to TB treatment, and Table 77-5.)

CASE 77-5, QUESTION 2: Why are the negative tuberculin skin test, negative sputum smears for AFB, and lack of cavitary lesions in C.J. still consistent with M. tuberculosis infection?

HIV-infected patients with CD4 counts less than 200 commonly present with extrapulmonary TB, along with or in the absence of pulmonary disease. These extrapulmonary sites include lymph nodes, bone marrow, spleen, liver, CSF, and blood.[12] The chest radiograph in HIV-infected patients may reveal hilar or mediastinal adenopathy or localized infiltrates in the middle or lower lung fields.

In HIV-infected patients, it is unusual to see typical apical infiltrates or cavitations. Furthermore, concomitant PCP may confuse the interpretation of chest radiographs. Finally, anergy (a state of immune unresponsiveness) is common in HIV disease. Thus, definitive diagnosis of TB rests on positive cultures from sputum or other tissue and body fluid specimens.[12] Unlike many other AIDS-related opportunistic infections, CD4 count is not a reliable predictor of an increased risk for TB diseases, and patients can have relatively high CD4 counts at the time of TB development.

HIV-INFECTED PERSONS: DRUG-SUSCEPTIBLE TUBERCULOSIS

CASE 77-6

QUESTION 1: K.D., a 26-year-old HIV-infected man, comes in for a routine clinic visit. It is discovered that he is a household contact of a person known to have active, untreated, drug-susceptible TB. His CD4 count is 350 cells/μL. A tuberculin skin test (five tuberculin units of PPD) is administered, and he is instructed to return to the clinic in 48 hours. His PPD has been negative in the past, and he has demonstrated delayed hypersensitivity responsiveness. How should the results of K.D.'s skin tests be interpreted, and should he be treated for latent TB considering his known exposure to TB?

Current guidelines recommend 9 months of isoniazid prophylaxis (300 mg/day PO) plus pyridoxine (50 mg/day PO) for all HIV-infected persons who have at least a 5-mm induration reaction to PPD and no evidence of active TB (negative chest radiograph and no clinical symptoms), unless otherwise contraindicated and regardless of Bacillus Calmette–Guerin vaccination status.[12] The administration of Bacillus Calmette–Guerin vaccine to HIV-infected persons is contraindicated because of the potential to cause disseminated disease.[12] A greater than 5-mm reaction in HIV-infected persons is considered positive.[12] Few isoniazid prophylaxis failures have been reported, although this finding has not been systematically studied. Additional preferred regimens in instances of questionable compliance include isoniazid 900 mg twice weekly plus pyridoxine 50 mg twice weekly for 9 months, both administered under direct observed therapy. Persons who cannot take isoniazid or who have been exposed to a known isoniazid-resistant strain should use either rifampin or rifabutin alone for 4 months as alternatives, being mindful of potential drug interactions with antiretroviral therapy.[12,108] All HIV-infected persons, irrespective of age, PPD results, or prior course of chemoprophylaxis, should be given chemoprophylaxis if they are in close contact with persons who have active TB. Prophylaxis also should be given for anergic, HIV-infected persons who have been in contact with patients known to have active TB.[108] Before the treatment of latent TB is begun, active TB needs to be ruled out. K.D. should undergo chest radiography and clinical evaluation to rule out active disease. The CDC no longer recommends routine anergy testing in these patients.[12]

Table 77-6

Recommendations for Coadministering Rifampin and Rifabutin with Non-nucleoside Reverse Transcriptase Inhibitors, Protease Inhibitors, and Integrase Inhibitors

Antiretroviral	Use in Combination With Rifabutin	Use in Combination With Rifampin	Comments
All ritonavir- and cobicistat-boosted protease inhibitors	Dose as 150 mg every day or 300 mg 3 × per	Do not coadminister	

	week. Therapeutic drug monitoring is recommended		
Fosamprenavir	Consider alternative ARV	Do not coadminister	
Atazanavir	Rifabutin 150 mg daily or 300 mg 3 × per week	Do not coadminister	
Nevirapine	Use caution at usual doses of rifabutin; however, there are no published clinical data	Do not coadminister	
Efavirenz	Rifabutin 450–600 mg daily or 600 mg 3 × per week unless coadministered with a protease inhibitor	Usual recommended dose of efavirenz is 600 mg daily. Some experts recommend increasing the efavirenz dose to 800 mg daily if efavirenz is used in combination with rifampin	
Etravirine	Rifabutin 300 mg daily unless coadministered with a boosted protease inhibitor, then do not coadminister	Do not coadminister	
Rilpivirine	Increase rilpivirine dose to 50 mg daily	Do not coadminister	
Maraviroc	Maraviroc 300 mg BID unless coadministered with a CYP3A4 inhibitor or inducer; rifabutin 300 mg daily	Coadministration not recommended; if used, then dose maraviroc 600 mg BID unless coadministered with a CYP3A4 inhibitor, then maraviroc 300 mg BID	
Raltegravir	No change in dosing	Raltegravir 800 mg BID and monitor closely for virologic response	
Dolutegravir	No change in dosing	Dolutegravir 50 mg BID unless INSTI resistance expected, then do not use with rifampin	
Elvitegravir/cobicistat/tenofovir/emtricitabine	Do not coadminister	Do not coadminister	

BID, twice a day; CYP3A4, cytochrome P-450 3A4.

HIV-INFECTED PERSONS: PROTEASE INHIBITORS, NONNUCLEOSIDE

REVERSE TRANSCRIPTASE INHIBITORS, CCR5 ANTAGONISTS, AND INTEGRASE INHIBITORS

CASE 77-7

QUESTION 1: F.C., a 36-year-old HIV-infected woman, diagnosed 6 months ago, was found to have active TB (pulmonary infiltrates on chest radiographs, sputum AFB stain and culture positive, and culture pansensitive). She is taking tenofovir, emtricitabine, atazanavir, ritonavir, and fluconazole, and her CD4 count is 300 cells/µL. What factors must be considered when selecting TB therapy for F.C.?

The use of protease inhibitors in the treatment of HIV-infected patients coinfected with TB increases the potential for drug interactions with rifamycin derivatives (rifampin and rifabutin). Because the rifamycins are potent inducers of the hepatic cytochrome P-450 system (e.g., CYP3A4), they can induce metabolism of the protease inhibitors, resulting in subtherapeutic levels. Conversely, the protease inhibitors elevate rifamycin serum levels by inhibiting their metabolism and increasing toxicities, such as rifabutin-associated uveitis (inflammation of the uveal tract of the eye; see Chapter 68, Tuberculosis).

According to recent guidelines, rifampin should not be coadministered with any standard protease inhibitors (boosted or not with ritonavir or cobicistat), etravirine, nevirapine, rilpivirine, or elvitegravir.[11,108] Rifampin may be used with efavirenz at the standard 600-mg once-daily dose with close monitoring for virologic response to antiviral therapy. Some clinicians recommend an 800-mg dose of efavirenz for patients weighing greater than 60 kg.[11,108] When using rifampin with raltegravir, the recommended dose of raltegravir is 800 mg BID, and patients should be monitored closely for virologic response. Coadministration of rifampin and maraviroc is not recommended, but if necessary, maraviroc

---

should be dosed 600 mg BID (or, if coadministered with a strong CYP3A inhibitor, maraviroc, 300 mg BID).[11] Dolutegravir should be dosed 50 mg twice daily if combined with rifampin.[11] Rifabutin should be given at 50% of the usual dose (i.e., reduced from 300 to 150 mg/day or 300 mg 3 times a week) with ritonavir- or cobicistat-boosted protease inhibitors.[11] Rifabutin should be given with efavirenz at dosages of 450 to 600 mg/day. Rifabutin can be used in full doses with nevirapine, etravirine, and rilpivirine; however, the rilpivirine dose should be increased to 50 mg daily.[108] If etravirine is coadministered with a ritonavir-boosted protease inhibitor, rifabutin should not be coadministered.[11] Tenofovir/emtricitabine/elvitegravir/cobicistat should not be coadministered with rifabutin; however, no dose adjustment is needed when combined with dolutegravir or raltegravir.[11] Sequential treatment of TB followed by HIV treatment is not recommended.[12] Three clinical trials have demonstrated a reduction in mortality and

HIV-related diseases when antiretrovirals are given during TB treatment.[109–111]

Discontinuing the protease inhibitor for F.C. is not an option considering the rapid viral replication and the risk of developing resistant isolates, especially considering that she recently was started on protease inhibitor therapy and is clinically responsive. A reduced dose of rifabutin (150 mg daily or 300 mg 3 times per week) is recommended when coadministered with atazanavir + ritonavir. Considering that F.C. is receiving atazanavir + ritonavir, she will be treated with a rifabutin-based regimen. She will receive isoniazid, rifabutin, pyrazinamide, and ethambutol daily for 8 weeks followed by isoniazid and rifabutin daily or 3 times weekly for 6 months.

MYCOBACTERIUM AVIUM COMPLEX DISEASE

Clinical Presentation

CASE 77-8

QUESTION 1: M.E., an HIV-infected 38-year-old woman with a history of IV drug use, presents with fevers, drenching night sweats, a poor appetite, and a 20-pound weight loss (>15% of baseline) during the past 4 months. M.E. has refused all antiretroviral therapy for the past year because of drug intolerance. She has a past medical history of recurrent herpes zoster, PCP, and cryptococcal meningitis. Her current medications include one TMP-SMX double-strength tablet once daily and an occasional valacyclovir dose when she feels the herpes zoster "is beginning to start"; she refuses MAC prophylaxis therapy. Physical examination reveals a cachectic woman with mild hepatosplenomegaly. Pertinent laboratory test results include the following:

Hematocrit, 23%
WBC count, 3,500 cells/L, with 68% neutrophils, 2% bands, 22% lymphocytes, and 8% monocytes
Absolute CD4 count, 25 cells/μL
Viral load, 200,000 copies/mL
Aspartate transferase, 135 international units/L
Alanine aminotransferase, 95 international units/L
Alkaline phosphatase, 186 international units/L

Skin testing reveals anergy. The chest radiograph is unremarkable. Based on these findings, a presumptive diagnosis of MAC infection is made. Why is M.E.'s clinical presentation consistent with MAC infection?

Disseminated MAC infection is common in end-stage AIDS patients. On autopsy, MAC organisms are observed in the lungs and multiple other bodily tissues.[112] The predominant organism in HIV-positive patients is M. avium (>95% of typeable isolates).[12] The risk of developing disseminated MAC infection is highest in patients with a CD4 count less than 50.[12] Poor prognostic indicators include prior OI, high plasma HIV RNA levels, previous colonization of the respiratory or GI tract with MAC, and reduced in vitro lymphoproliferative immune responses to M. avium antigens.[12]

M. avium is a ubiquitous organism found in food, water, soil, and house dust. The most likely portal of entry is either the GI or respiratory tract. Common presenting symptoms associated with MAC infection include fever, night sweats, anorexia, malaise, profound weight loss (>10% body weight), anemia, lymphadenopathy, and diarrhea.[12] M.E.'s fevers, drenching night sweats, poor appetite, 20-pound weight loss, and mild hepatosplenomegaly are consistent with MAC infection. In particular, her CD4 count of 25 puts her at a risk for this OI.

Treatment

INITIATION

CASE 77-8, QUESTION 2: Why is it appropriate to initiate M.E.'s drug therapy before blood culture results have documented the presence of MAC?

Disseminated MAC is best diagnosed by peripheral blood cultures. However, initial testing often includes AFB on a blood smear.[12] Conventional culture methods using solid media may have a turnaround time of as long as 8 weeks; however, radiometric broth systems signaling the release of carbon 15-labeled CO_2 from mycobacteria may detect bacterial growth in 7 to 10 days.[113] Identification of the organism (M. tuberculosis vs. atypical mycobacteria) by conventional biochemical methods may take weeks to months. Techniques using DNA probes make diagnosis possible within several hours.[113] Quantitative blood cultures have been useful to monitor the effects of drug therapy but may not be practical on a routine clinical basis. Radiometric broth methods also may provide in vitro drug susceptibility in another 7 to 10 days. Even with the availability of all of these laboratory tests, results generally are not available for 2 to 3 weeks. In view of this lag time, empiric therapy should be initiated as quickly as possible. Although MAC is typically isolated from blood, the organism can also be demonstrated via acid-fast smears of lymph node, liver, or bone marrow biopsies. Because these organs are rich in monocytes (the target cells for MAC infection), the organism load may be high (up to 10^{11} colony-forming units/mL).

DRUG SUSCEPTIBILITY AS A BASIS FOR TREATMENT

CASE 77-8, QUESTION 3: Should M.E.'s therapy be based on in vitro drug susceptibility results?

Correlation between in vitro drug susceptibility results and clinical efficacy has not been clearly established for MAC.[113],[114] In addition, drug susceptibility studies also may not correlate with clinical efficacy because in vitro results for individually tested drugs may show resistance, but combination therapy may be additive or synergistic. Finally, some antimycobacterial agents exhibit large differences between the minimum inhibitory concentration and maximum bactericidal concentration. This finding may reflect the difficulty in eradicating this organism, particularly in a severely immunocompromised host. Despite these limitations, in vitro drug susceptibility testing is only recommended for macrolide antibiotics because of the correlation with clinical outcomes.[115]

DRUG THERAPY

CASE 77-8, QUESTION 4: What drug regimens could be selected to treat M.E.?

The guidelines recommend a two-drug or more MAC regimen, because monotherapy can lead to breakthrough bacteremia and resistance; at least one of these drugs must be a macrolide. Clarithromycin (500 mg PO BID) is the preferred agent because there are more clinical data; however, if intolerable or significant drug interactions need to be avoided, azithromycin 500 to 600 mg PO QD is an alternative. Doses of clarithromycin greater than 1 g/day in the treatment of MAC have been associated with increased mortality.[12] Ethambutol (15 mg/kg/day PO) is recommended as the second agent. Several drugs can be used as the third agent, including rifabutin (300 mg/day), amikacin (10–15 mg/kg/day), and fluoroquinolones. The choice of the third agent depends on the severity of the illness including high mycobacterial loads, CD4 count less than 50, drug interactions, hepatic and renal function, patient tolerability, patient compliance, and cost. Long-term therapy may be discontinued in patients who have completed a course of more than 12 months of treatment for MAC, remain asymptomatic, and have a sustained increase (e.g., >6 months) in their CD4 count to greater than 100 after HAART.[12]

Although four-drug regimens have been used, one study observed that a three-drug macrolide regimen (clarithromycin, ethambutol, and rifabutin) was more effective than a four-drug regimen (ciprofloxacin, clofazimine, ethambutol, and rifampin).[116] Benefits of the macrolide regimen included more rapid clearing of MAC bacteremia and a longer duration of survival. Rifabutin, at 600 mg/day, induced uveitis in approximately one-third of patients. Subsequently, the rifabutin dosage was lowered to 300 mg/day, and the incidence of uveitis decreased to 5.6%. Although clearance of bacteremia was superior at the higher rifabutin dose, no differences in survival were observed.

IRIS can also occur with MAC disease. IRIS-associated fever and lymphadenitis are difficult to differentiate from active MAC disease. IRIS most commonly occurs in patients with MAC and very low CD4 counts with the initiation of antiretroviral therapy. The disease is often self-limiting and requires no therapy; however, steroid therapy may be warranted in severe disease. For this reason, for patients not taking antiretroviral therapy, it may be warranted to administer MAC therapy for 2 weeks before the initiation of antiretroviral therapy to minimize the risk of IRIS.[12]

M.E. is placed on a regimen of clarithromycin 500 mg twice daily and ethambutol 15 mg/kg/day. The choice to use two drugs, rather than three, is based on M.E.’s poor adherence profile. Other considerations for the addition of a third-line agent include the severity of the illness, potential drug interactions, tolerability, hepatic and renal function, and cost. M.E. must be counseled regarding the slow response to treatment. If she improves, therapy should be continued and HAART should be reinstituted.

Monitoring Therapy

CASE 77-8, QUESTION 5: How should M.E. be monitored?

The primary goals of MAC therapy are to eradicate or reduce the number of M. avium organisms, decrease symptoms, enhance quality of life, and prolong survival. M.E. should be monitored for symptomatic relief (temperature spikes and frequency of night sweats), as well as a microbiologic response (colony-forming units/mL). Clinical response, as well as a decline in the quantity of mycobacteria, is expected in 2 to 4 weeks but may be delayed in patients with extensive disease. If no clinical response is seen in 4 to 8 weeks, repeat blood cultures for MAC should be obtained along with repeat susceptibility testing for clarithromycin and azithromycin. If resistance is observed or suspected, two new drugs should be added based on susceptibility testing with or without the macrolide. If the organism is found to be susceptible to macrolides, therapy should be continued and adherence, absorption, tolerance, and drug interactions should be considered.[12] If the problem is determined to be drug absorption, IV agents can be considered. M.E. should also be followed for the development of toxicities related to drug therapy. Furthermore, because many drugs used to treat MAC infections are associated with drug interactions, this issue must be considered each time a new drug is prescribed. In some cases, drug doses need to be modified or alternative drugs should be selected to prevent adverse events or therapeutic failures.[12],[115]

CASE 77-8, QUESTION 6: What drug(s) should be used to provide primary prophylaxis against MAC infection?

Prophylaxis

The most recent official guidelines recommend oral therapy with clarithromycin (500 mg BID) or azithromycin 1,200 mg every week or 600 mg twice weekly for persons with a CD4 count less than 50. Although the combination of azithromycin and rifabutin is more effective than azithromycin alone, the increased cost, adverse events, potential for drug interactions with rifabutin, and the absence of a survival benefit preclude this regimen from being routinely recommended. If neither clarithromycin nor azithromycin is tolerated, rifabutin 300 mg/day may be used (Table 77-1).[12]

Six hundred eighty-two patients with AIDS, CD4 counts less than 100, and negative MAC blood cultures were randomly assigned to receive clarithromycin

(500 mg PO BID) or placebo.[33] The clarithromycin arm had a 69% reduction in MAC bacteremia and fewer (16% vs. 6%) cases of MAC infection. Significantly more patients in the clarithromycin arm survived during the 10-month follow-up (68% vs. 59%), with an accompanying longer median duration of survival. This trial was the first prospective MAC prophylaxis study demonstrating a survival benefit and a reduced risk of disseminated MAC infection.[33]

Azithromycin 1,200 mg every week, rifabutin 300 mg/day, and a combination of both drugs in the same doses were compared in patients with AIDS and CD4 counts less than 100. The incidence of MAC bacteremia was 13.9% in the azithromycin monotherapy arm, 23.3% in the rifabutin monotherapy arm, and 8.3% in the azithromycin plus rifabutin combination arm. Time to death was not significantly different among the treatments; however, the combination arm had an increased incidence of adverse drug effects. Although combination therapy was superior to azithromycin alone, its use is considered second-line therapy because of the increased cost, toxicity, and lack of survival benefit.[117]

The decision to use clarithromycin or azithromycin (both first-line recommendations for primary prophylaxis) is based on patient compliance and the potential for drug interactions. Azithromycin (1,200 mg once weekly or 600 mg twice weekly) may be preferable for a patient who has difficulty with compliance. In contrast to clarithromycin, azithromycin does not affect the cytochrome P-450 enzyme system and is therefore less likely to interact with other drugs. M.E. would have benefited from MAC prophylaxis when her CD4 count decreased to less than 50.

Patients whose CD4 count increases from 100 for more than 3 months may discontinue primary prophylaxis (Table 77-2). However, prophylaxis should be reintroduced if the CD4 count decreases to less than 100.[12]

MUCOCUTANEOUS CANDIDIASIS

CASE 77-9

QUESTION 1: P.J. is a 45-year-old, HIV-positive man who was started on abacavir, lamivudine, and darunavir/cobicistat when he was diagnosed 1 year ago. P.J. is a heroin user and has not been seen in the clinic since his initial presentation. He appears today complaining of difficult, painful swallowing and diffuse pain. On examination, localized white plaques are observed in the oral cavity. His CD4 count is 280 cells/μL. What is the most likely cause of this patient's dysphagia and odynophagia?

Candida can cause both oropharyngitis and esophagitis in HIV-infected patients typically when CD4 counts are <200 cells/μL. Additionally, patients can present with CMV, HSV, or aphthous ulcers in the oropharynx. Symptoms include dysphagia, odynophagia, and thrush (with Candida infections). Oral ulcers are common with HSV, rare with Candida, and uncommon with CMV or aphthous ulcers. Pain is usually diffuse in Candida infections and more focused with HSV, CMV, and aphthous ulcers. Fever is primarily associated with CMV.[12]

Most infections are due to Candida albicans; however, because of the exposure of fluconazole, emergence of non-albicans species such as Candida glabrata has appeared and in some cases led to refractory candidiasis.[12] Patients with localized white plaques in the oral cavity likely have oral candidiasis (thrush) and should be started on antifungal therapy. Oral fluconazole (100 mg once daily) is considered the drug of choice for the treatment of oropharyngeal candidiasis because it is more convenient and better tolerated than topical therapies. Patients may also be treated with local antifungal therapy (e.g., “swish and swallow” nystatin suspension, 1 teaspoon 4 or 5 times daily, or clotrimazole troches 4 or 5 times daily). The preferred therapy for esophageal candidiasis is 14 to 21 days of fluconazole at higher doses (up to 400 mg PO or IV daily). Alternate therapies include itraconazole and posaconazole (for oropharyngeal disease) and voriconazole, anidulafungin, caspofungin, micafungin, and amphotericin B (for esophageal disease).[13] Primary prophylaxis is not recommended for candidiasis.[12]

A presumptive diagnosis of Candida esophagitis can be made for P.J. because he presents with oral pharyngeal candidiasis, dysphagia, and odynophagia. P.J. should be empirically treated with fluconazole 200 mg/day for 14 to 21 days. If he is unresponsive to fluconazole, endoscopy with biopsy and culture should be performed to confirm the diagnosis as well as Candida speciation. If candidiasis is confirmed, P.J. should be checked for medication adherence and potential drug interactions. If the patient is adherent and does not have malabsorption, posaconazole suspension or itraconazole solution should be considered. In addition, higher doses of fluconazole could be considered before the initiation of alternative IV therapy. Relapse is common in patients who do not receive secondary prophylaxis. Chronic suppressive therapy (fluconazole, 100–200 mg/day) could be considered in patients responsive to fluconazole therapy who have frequent or severe recurrent esophagitis; however, the risks of fluconazole resistance should be considered.[12]

Fungal Infections

John D. Cleary and Russell E. Lewis

CORE PRINCIPLES		CHAPTER CASES
1	Owing to increased numbers of immunocompromised patients, the use of invasive devices, and an aging patient population, invasive fungal infections are the fourth most common nosocomial infection.	
2	Yeast infections are generally easier to treat than mold infections. However, mortality is still significant for both types of infection, even when treated appropriately.	**Table 78-2**
3	Most common risk factors for acquiring mycotic infections include immunocompromised host, the use of broad-spectrum antibacterials, and breakdown of physical barriers including invasive catheterization.	**Case 78-3 (Questions 1,3)**
4	Diagnostic tools (i.e., serum galactomannan or β-glucan) can be useful as monitoring parameters for therapeutic outcome assessment.	**Case 78-3 (Question 2)**
5	The Infectious Disease Society of America (IDSA) and the Mycoses Study Group are important sources for guidelines and evidence-based approaches to therapy.	**Case 78-5 (Question 1)**
6	Dermatophyte infection is most commonly associated with Tinea ringworm, and the most effective antifungal agents include itraconazole and terbinafine.	**Case 78-1 (Questions 1–3)**
7	Sporothrix is one of the most common fungal pathogens associated with subcutaneous infections. Amphotericin, terbinafine and itraconazole are useful treatments.	**Case 78-2 (Questions 1–3),** **Figure 78-1**
8	Candida represents the most common cause of systemic fungal infection in hospitalized patients. Candidemia must be treated promptly and appropriately. Delay in treatment or failure to adhere to IDSA guidelines results in a significant increase in mortality. Fluconazole and echinocandins are the most recommended prephylaxis and therapies for disseminated candidiasis.	**Case 78-3 (Questions 1–4, 11),** **Table 78-4–78-6**
9	Fluconazole, although reliable against Candida albicans, is less reliable against certain non-albicans Candida species, including Candida glabrata and Candida krusei.	**Case 78-3 (Question 5)**
10	Conventional amphotericin is associated with significant infusion-related adverse events, nephrotoxicity, and electrolyte abnormalities.	**Case 78-3 (Questions 6–10),** **Table 78-3**

	Consequently, other agents, including lipid-based amphotericin B, triazoles, and echinocandins, are drugs of choice for most deep-seated fungal infections.	
11	In patients with yeast identified in urine, the selection of drug therapy for a simple candiduria versus organ infection as a result of disseminated candidiasis is complicated by difficulties with diagnostics.	**Case 78-4 (Question 1)**
12	Blastomycosis, histoplasmosis, and coccidioides are associated with endemic infection from specific geographic areas. Long-term treatment with polyenes and/or azole antifungals is useful in the management of these diseases.	**Case 78-5 (Questions 1–3), Case 78-6 (Questions 1–3), Case 78-7 (Questions 1–3), Figures 78-2–78-4, Table 78-7**

13	Aspergillus is the most significant fungal pathogen associated with severely immunocompromised patients. Aggressive, immediate treatment with voriconazole alone or in combination with other antifungals is the most effective therapy for disseminated disease.	**Case 78-8 (Questions 1–3), Figure 78-5, Table 78-8**
14	Cryptococcus neoformans is associated with opportunistic infection, particularly in acquired immunodeficiency syndrome (AIDS), and the central nervous system (CNS) is a common site of infection. Initial treatment of meningitis in AIDS should include amphotericin B plus flucytosine, followed by long-term fluconazole.	**Case 78-9 (Questions 1–3)**

Mycotic (fungal) infections are now the fourth most commonly encountered nosocomial infection. Attributable mortality associated with invasive yeast infections can approximate ~40%, whereas molds typically double that observed rate (i.e., invasive aspergillosis). This increase can be attributed, in part, to the growing numbers of immunocompromised hosts as a result of organ transplants, cancer-chemotherapy–associated neutropenia, and AIDS. This chapter reviews the mycology, diagnosis, and pharmacotherapeutics for common mycotic infections. For a more in-depth presentation of the basic biology of fungi, as well as the epidemiology, pathogenesis, immunology, diagnosis, and monitoring of mycotic infections, see Clinical Mycology.[1] You are referred to other chapters including Chapter 65, Central Nervous System Infections; Chapter 66, Endocarditis; Chapter 70, Intra-Abdominal Infections; Chapter 73, Osteomyelitis and Septic Arthritis; Chapter 75, Prevention and Treatment of Infections in Neutropenic Patients; Chapter 76, Pharmacotherapy of Human Immunodeficiency Virus Infection; and Chapter 77, Opportunistic Infections in HIV-Infected Patients for detailed pharmacotherapy in these human pathologies.

MYCOLOGY

Morphology

The pathogenic fungi that infect humans are nonmotile eukaryotes that are reproduced by sporulation, and they exist in two forms: filamentous molds and unicellular yeasts. These forms are not mutually exclusive, and depending on the growth conditions, a fungus may exist in one or even both of these forms (Table 78-1).

The dimorphic fungi (e.g., Histoplasma capsulatum and Blastomyces dermatitidis) grow as a mold in nature (27°C) but quickly convert to the pathogenic yeast form after infecting the host (37°C). This mycelium-to-yeast conversion is an important factor in the pathogenesis of disease caused by these organisms. Other pathogenic fungi, such as Aspergillus species, grow only in a mold form, whereas C. neoformans usually grows in a yeast form. Candida species grow with a modified form of budding whereby newly budded cells remain attached to the parent cells and form pseudohyphae. Fungi are aerobic and are easily grown on routine culture media similar to that used to grow bacteria. Most fungi grow best at 25°C to 35°C. Fungi that cause only cutaneous and subcutaneous disease grow poorly at temperatures greater than 37°C. This temperature-selective growth explains, at least in part, why these organisms rarely disseminate from a primary focus in the skin or subcutaneous tissues.

Classification

Fungal infections are best classified by the area of the body infected (Table 78-2). Superficial mycoses involve only the outermost keratinized layers of the skin (stratum corneum) and hair. The cutaneous mycoses extend deeper into the epidermis and may also infect the nails. The subcutaneous mycoses infect the dermis and subcutaneous tissues; entry into these sites is by the inoculation or implantation of dirt or vegetative matter. The systemic mycoses cause disease of the internal organs of the body. Standard definitions that are useful in daily patient care for invasive fungal infections have been developed for epidemiologic and clinical trials. The guidelines are referenced under each infection. The respiratory tract is the most common primary portal of entry, and lung infection may be symptomatic or asymptomatic. Systemic infection with Candida usually results from a primary focus on the gastrointestinal (GI) tract or skin. In each case, the organism may spread hematogenously from the primary focus throughout the body, resulting in disseminated disease. The opportunistic mycoses occur primarily in the immunocompromised host and require immediate and aggressive treatment. The list of fungi that cause opportunistic infection has expanded, especially with the AIDS epidemic; however, the now commonplace use of highly active antiretroviral therapy has resulted in some decrease in this incidence.[2] The nonopportunistic fungi (primary pathogens) usually cause disease in the immunologically normal host. Some primary pathogens, however, result in unique clinical syndromes when infection occurs in the immunocompromised host, such as histoplasmosis in AIDS.[1]

Table 78-1

Organism Classification

Hyphae (Molds)
Hyalohyphomycoses Aspergillus species, Pseudallescheria boydii Dermatophytes: Epidermophyton floccosum, Trichophyton species, Microsporum species **Phaeohyphomycoses** Alternaria species, Anthopsis deltoidea, Bipolaris hawaiiensis, Cladosporium species, Curvularia geniculata, Exophiala species, Fonsecaea pedrosoi, Phialophora species, Fusarium species **Zygomycetes** Rhizopus spp., Mucor spp., Rhizomucor spp. Absidia corymbifera
Dimorphic Fungi
Blastomyces species, Coccidioides species, Paracoccidioides species, Histoplasma species, Sporothrix species
Yeasts
Candida species, Cryptococcus neoformans

Pathogenesis of Infection

ENDOGENOUS

Fungal infection can be acquired from both exogenous and endogenous sources. The only pathogenic fungi identified as commensals within the human microbiome are Pityrosporum orbiculare, which causes the noninflammatory superficial condition of tinea versicolor, and Candida species. Infections with these yeasts primarily develop from the patient’s own normal flora (endogenous infection). These endogenous fungal infections of the skin or mucous membranes generally occur when host resistance is lowered and the organism proliferates in high numbers. Excess heat and humidity, oral contraceptive use, pregnancy, diabetes, malnutrition, and immunosuppression facilitate endogenous local infection by both Pityrosporum and Candida. Systemic candidal infections occur in the immunocompromised or genetic deficient host (Table 78-2)[3,4] when the organism colonizing the patient’s skin or GI tract disseminates hematogenously throughout the body.

Table 78-2

Clinical Classification of Mycoses

Classification	Site Infected	Example	Potential Gene Deficiency
Superficial	Outermost skin and hair	Malasseziasis (tinea versicolor)	
Cutaneous	Deep epidermis and nails	Dermatophytosis	
Subcutaneous	Dermis and subcutaneous tissue	Sporotrichosis	
Systemic	Disease of more than one internal organ		
Opportunistic		Candidiasis	Mannose-binding Lectin-1 Toll-like Receptor 4
		Cryptococcosis	Dectin-1
		Aspergillosis	
		Mucormycosis	
Nonopportunistic		Histoplasmosis	
		Blastomycosis	
		Coccidioidomycosis	Interferon-γ receptor 1 Dectin-1 Mannose Binding Lectin-1

EXOGENOUS

Exogenous infections occur when the fungus is acquired from an environmental source. In the case of dermatophytes (ringworm fungi), the organism can be acquired from dirt, animals, or another infected individual. The subcutaneous mycoses result from direct inoculation of infected material, often a thorn or other vegetable matter, through the skin. Infections of the skin and subcutaneous tissues by Aspergillus and zygomycetes (e.g., Rhizopus, Absidia, and Mucor) have resulted from contaminated wound dressings and cast materials.[1,5] Drug-induced disease has been observed secondary to Saccharomyces cerevisiae (nutraceutical) administration to healthy and immunocompromised patients or secondary to the administration of a contaminated sterile product (i.e., Exserohilum rostratum).

Exogenous fungi colonized or carried on the hands of health-care workers can infect patients; therefore, handwashing is emphasized for health-care workers, particularly in critically ill patients.[6] Other than candidal infections, the systemic mycoses are primarily the result of inhalation of dust contaminated by the infectious spores, with a primary focus of infection in the lungs.

If local or systemic host defenses do not control the primary infection, the organism can spread hematogenously to other organs. Some of the systemic mycoses have defined geographic (endemic) areas where the fungus is more commonly encountered. For example, histoplasmosis and blastomycosis occur most often in the regions of the Red, Mississippi, and Ohio River valleys, whereas coccidioidomycosis is endemic to the southwestern United States and the Central Valley of California.

Host Defenses

Host defenses against fungal infection involve both nonimmune (also known as nonspecific or natural resistance) and immune (also known as specific or acquired resistance) mechanisms. Nonimmune resistance plays a primary role in preventing colonization and invasion of a susceptible tissue. The normal bacterial flora of the skin and mucous membranes prevent colonization (colonization resistance) by more pathogenic bacteria and fungi. Patients treated with broad-spectrum antibiotics are at a greater risk for colonization and infection by fungi. The barrier function of the intact skin and mucous membranes is also an important defense. Skin defects (intravenous [IV] catheters, burns, surgery, or trauma) are risk factors for local invasion and fungemia, especially with Candida species. The translocation of yeast from the gut into the peritoneum during the trauma of a motor vehicle accident or post-GI surgery is also commonly associated with these infections. When these physical barriers are breached, the polymorphonuclear leukocyte (neutrophil) and monocytes along with defensive lectins (i.e., mannose-binding protein) provide early host defense. The antifungal activity of neutrophils involves phagocytosis and intracellular killing but also can include extracellular killing by secreted lysosomal enzymes. Neutropenia is the most common neutrophil defect predisposing to fungal infection, but functional defects of neutrophils, such as those occurring in patients with chronic granulomatous disease of childhood and myeloperoxidase deficiency, have also been associated with an increased frequency of fungal infections, especially with Candida and Aspergillus. Finally, endothermy/homeothermy and ultimately febrile responses are potent nonspecific immune defenses.

Antibody and complement have a potential role in the prevention of certain fungal infections, but they are not the primary effectors of acquired resistance. Cellular immunity, mediated by antigen-specific T lymphocytes, cytokines, and activated macrophages, is the primary acquired (immune) host defense against fungi. Patients with defective cellular immunity (e.g., immunosuppressed organ transplant recipients, patients with lymphoma and leukemia, patients with AIDS, and those treated with corticosteroids or cytotoxic agents) are at a greatest risk for fungal infection. Severe immunodeficiency often results in poor therapeutic outcome despite appropriate antifungal therapy. An additional factor associated with an increased risk for fungal infection is the use of total parenteral nutrition (TPN).[1] Interestingly, patients with specific T-cell dysfunction (i.e., HIV infection) appear to be at an isolated risk for mucosal Candida infection, but not systemic infections.

ANTIMYCOTICS

Mechanisms of Action

Table 78-3 lists the US Food and Drug Administration (FDA)-approved topical and systemic antimycotics for the treatment of fungal infections. Griseofulvin and potassium iodide have limited clinical utility and are not used to treat systemic fungal infections. Griseofulvin inhibits growth by inhibiting fungal cell mitosis caused by the polymerization of cell microtubules, thereby disrupting mitotic spindle formation. It has activity only against the dermatophyte fungi. The antifungal mechanism of potassium iodide is unclear. It is effective only in the treatment of lymphocutaneous sporotrichosis.

The 12 antifungal drugs used commonly for systemic disease fall into five structural classes that act by four mutually exclusive mechanisms. Amphotericin B (AmB) and nystatin (a polyene macrolide) act principally by binding to ergosterol in the fungal cell membrane, effectively creating pores in the cell membrane and leading to the depolarization of the membrane and cell leakage.[7] AmB binds with greater affinity to ergosterol than to cholesterol.[8] This phenomenon is believed to be mediated through both hydrophilic hydrogen bonding and hydrophobic, nonspecific van der Waals forces. Investigations using P^{32} nuclear magnetic resonance spectroscopy document that the presence of the double bond in the side chain of ergosterol (not present in cholesterol) accounts for the greater affinity of AmB for ergosterol.[7] AmB, however, also binds to sterols of mammalian cells (i.e., cholesterol), which may account for most of the toxic effects of AmB or reduced toxicity (i.e., circulating cholesterol). Alteration in the lipid content of the pathogens membrane may play a role in the development of resistance,[9] although other factors are also important.[10] The cidal antifungal effects of AmB are, however, not only owing to cell leakage resulting from ergosterol binding, but also owing to immune stimulation and oxygen-dependent killing.[8,11]

5-Flucytosine, a fluorinated cytosine analog, acts principally by inhibiting nucleic acid synthesis. It is actively transported into susceptible cells by the enzyme cytosine permease, where it is deaminated to the toxic metabolite 5-fluorouracil. Fluorouracil, when converted to 5-fluorouridine triphosphate, functions as an antimetabolite. It is incorporated into fungal RNA, where it is substituted for uracil and thereby disrupts protein synthesis. 5-Fluorouracil can also be converted to fluorodeoxyuridine monophosphate, which inhibits thymidylate synthase and thus disrupts DNA synthesis.[12]

The azole antifungals and the allylamines (naftifine and terbinafine) inhibit sterol biosynthesis by interference with either cytochrome (CYP) P450–dependent lanosterol C14-demethylase (azoles) or squalene epoxidase (allylamines), critical enzymes in the biosynthesis of ergosterol.[13,14] The superior affinity of the triazoles (fluconazole, itraconazole, isavuconazole, posaconazole, and voriconazole) for fungal versus mammalian enzymes, as compared with the imidazoles (ketoconazole and miconazole), accounts for their reduced toxicity and improved efficacy.[13] The consequence of sterol biosynthesis inhibition is a faulty cell membrane with altered permeability. In general, the allylamines and older azoles are fungistatic. The newer triazoles (voriconazole and posaconazole) demonstrate fungicidal activity against some fungal species. The clinical relevance of in vitro fungicidal versus fungistatic action is the subject of considerable debate. Nevertheless, it seems logical that fungicidal action, if it can also be achieved in vivo, is preferred in immunosuppressed hosts.[15]

Table 78-3

Antifungal Agents Approved for Use

Agent (Brand Name)	Formulation
Systemic Agents	
Amphotericin B (Abelcet, AmBisome, Amphotec)	IV
Amphotericin B-deoxycholate (generic)	IV
Anidulafungin (Eraxis)	IV
Caspofungin (Cancidas)	IV
Fluconazole (Diflucan)	IV, tablet, oral suspension
Fluorocytosine [Flucytosine] (Ancobon)	Capsule
Griseofulvin (generic)	Tablet, oral suspension
Isavuconazole (Cresemba)	IV, oral capsule
Itraconazole (Sporanox)	IV, capsule, oral solution
Ketoconazole (Nizoral)	Tablet
Micafungin (Mycamine)	IV
Posaconazole (Noxafil)	IV, oral suspension, oral gastroresistant tablet
Potassium iodide	Solution
Terbinafine (Lamisil)	Tablet, oral granules
Voriconazole (Vfend)	IV, tablet, oral suspension
Topicals, Class I	
Amphotericin B	Cream, lotion, ointment, oral suspension[a]
Butenafine (Lotrimin Ultra)	Cream
Butoconazole (Gynazole)	Vaginal cream
Ciclopirox (Loprox)	Cream, gel, lotion, shampoo, solution, suspension
Clioquinol (Vioform)	Cream, ointment
Clotrimazole	Cream, lotion, lozenge, solution, tablet, vaginal cream
Econazole (Spectazole)	Cream
Ketoconazole (Nizoral)	Cream, foam, gel, shampoo
Miconazole	Aerosol liquid and powder, buccal tablet, cream, lotion, ointment, powder, suppository, vaginal tablet

Naftifine (Naftin)	Cream, gel
Nystatin	Cream, mouthwash, ointment, powder, suspension, tablet
Oxiconazole (Oxistat)	Cream, lotion
Povidone iodine	Aerosol, douche, gel, ointment, solution, suppository
Sodium thiosulfate (Exoderm)	Lotion
Sulconazole (Exelderm)	Cream, solution
Terbinafine (Lamisil)	Cream, spray
Terconazole (Terazol 7)	Cream, suppository
Tioconazole (Vagistat)	Ointment
Tolnaftate (generic)	Aerosol, cream, gel, powder, solution
Undecylenic acid	Powder

[a] No longer available in the United States.

IV, intravenous.

Lipopeptides, which are potent antifungal agents, include the structural class of echinocandins (anidulafungin, micafungin, and caspofungin). All share a common mechanism. They act by interfering with 1,3-β-D-glucan, preventing the synthesis of essential cell wall polysaccharides that protect the cell from osmotic and structural stresses. The result is inhibition of fungal cell wall biosynthesis. Targeting the cell wall (as opposed to the cell membrane, which is the target of polyene, azole, and allylamine antifungals) imparts greater selectivity for fungal versus mammalian cells; thus, echinocandins class of antifungals has fewer toxicities than other antifungal classes.[16]

Antifungal Spectrum and Susceptibility Testing

The Clinical and Laboratory Standards Institute (CLSI) recommends standardized broth dilution (M27-A3) and disk diffusion (M44-A2, M44-S3, and M51-A) methods for determining in vitro antifungal susceptibilities for yeasts.[17] These methods stipulate test medium, inoculum size and preparation, incubation time and temperature, end-point reading, and quality control limits for AmB, flucytosine, fluconazole, ketoconazole, and itraconazole. Minimum inhibitory concentration (MIC) values for use in clinical interpretation are specified for fluconazole, voriconazole, itraconazole, flucytosine, and the echinocandins against Candida species after 24 hours of incubation. For azole, a susceptible-dose-dependent (S-DD) break point was developed based on data supporting a trend toward better response with higher drug concentrations for isolates with higher MIC.[18] The fluconazole S-DD range is 4 to 8 mcg/mL for C. albicans, Candida parapsilosis, and

Candida tropicalis and ≤32 mg/L for C. glabrata. Itraconazole and voriconazole S-DD ranges are 0.25 to 0.5 mg/L for C. albicans. Owing to the rapid development of resistance and limited data on correlation of MIC with outcome for flucytosine monotherapy, proposed interpretive break points for this agent are based on a combination of historic data and results from animal studies. Candida isolates with a flucytosine MIC ≤4 mcg/mL are considered susceptible, and isolates with MIC >16 mcg/mL are considered resistant. Limitations of the M27-A methodology have precluded the development of AmB interpretive break points nor have interpretive criteria been proposed for ketoconazole MIC. Candida are generally susceptible to MIC <0.25 mcg/mL and resistant to >1 mcg/mL, except for C. parapsilosis and Candida guilliermondii that have higher susceptibility (<2 mcg/mL) and resistant (>8 mcg/mL) values. Commercial kits are available for antifungal susceptibility testing, which utilize broth microdilution, colorimetric, and agar-based techniques.[19–21] University of Texas Health Science Fungal Testing Laboratory has historically tested fungi susceptibilities and reports current break points and epidemiologic cutoff values.

An E-Test (AB Biodisk; Piscataway, NJ) is a commercially available antifungal gradient strip. Difficulties in end point determination using this method result from frequent, nonuniform growth of the fungus on the agar medium; yet, when properly performed, correlation between the E-Test and M27-A methods has been satisfactory for the azole antifungal agents against most Candida.[19] Other techniques under development for antifungal susceptibility testing for yeasts include flow cytometry and direct measurement of alterations in ergosterol synthesis.[20] Flow cytometry detects the activity of the test antifungal drug through identification of subtle dosage–response effects on specific cell parameters as cells within the prepared inoculum pass through a beam of light. Test results may be available in as few as 4 hours. Interlaboratory reproducibility or correlation between test results and clinical outcomes has not been well studied.[21]

The CLSI-recommended standardized broth dilution method for determining in vitro antifungal susceptibilities for certain spore-producing molds, namely Aspergillus species, Fusarium species, Rhizopus species, Pseudallescheria boydii, and Sporothrix schenckii, is the M38-A2 method.[15] An E-Test to evaluate mold susceptibilities is also commercially available (AB Biodisk) and correlates well with the CLSI M38-A method for AmB and itraconzole.[22] Colorimetric microdilution, flow cytometry, and agar-based testing methods are under development. Despite these recent advances, the determination of in vitro susceptibilities or resistance in clinical practice is of limited utility and not readily available for yeasts or molds in most institutions.

Susceptibility testing for clinical isolates is not routinely recommended because susceptibility is usually predictable. However, published data on the susceptibility of the identified species of yeasts or molds should guide the clinician’s therapeutic choice. Clinical isolates from patients failing high-dose therapy (i.e., refractory oral pharyngeal candidiasis) or unusual pathogenic yeasts in patients with AIDS can be sent for testing.[20] Testing should be performed in a laboratory where the staff is trained in mycoses. Despite these limitations, certain patterns are common. First, AmB has broad in vitro activity and clinical efficacy against the yeasts and filamentous molds. The echinocandins have cidal activity in vitro versus Candida species and static activity for Aspergillus species; they are not active in vitro against Cryptococcus species and many endemic mycoses.[23] The azole antifungals are generally reliable against the yeasts and most dimorphic fungi. Additionally, itraconazole, voriconazole, and posaconazole have excellent in vitro activity against Aspergillus species, with associated clinical efficacy. Unlike other azoles, posaconazole and isavuconazole have some activity in vitro and reported clinical evidence of efficacy against zygomycetes, for which previously only AmB formulations were therapeutic options.[24,25]

Routine susceptibility testing of fluconazole, voriconazole, and an echinocandin against C. glabrata is increasing recommended, especially for isolates from blood normally sterile fluids, tissue, or abscess owing to recent reports of increasing echinocandin and multidrug resistance.[26–28] Additionally, any patient with invasive disease and clinical failure of initial therapy should be considered for susceptibility following consultation with an experience microbiologist.

New Frontiers for Antifungal Therapy

Various investigative efforts have been directed toward enhancing efficacy, reducing the toxicity, and improving the oral bioavailability of older antifungal drugs. Aerosol delivery of AmB products, itraconazole, voriconazole, and caspofungin in immunocompromised patients has been investigated for the prevention of invasive pulmonary aspergillosis. Reduction in invasive pulmonary aspergillosis was demonstrated in a randomized, placebo-controlled trial of aerosolized liposomal AmB.[29] Additional well-designed clinical trials are still needed to establish the role of aerosolized delivery of antifungal agents. Optimal antifungal dose and nebulized system required for effective prophylaxis have yet to be established compared with traditional GI regimens (Table 78-4).[29–31]

Table 78-4

Antimycotic Prophylaxis Regimens and Approximate Costs

Agent	Dose/Day	Formulation	Recommended Regimen	Cost ($)/day[a]

Selective GI Decontamination				
Amphotericin B	400 mg	Oral suspension	Swish and swallow QID	9.75
Nystatin	4–12 million units	Oral suspension	Swish and swallow QID	38.50–115.25
Systemic				
Clotrimazole	30–80 mg	Troche	TID–QID	125–450
Ketoconazole	200–400 mg	Oral	Daily	0.75–1.50
Itraconazole	200–400 mg	Oral	Daily	18–36.25
Fluconazole	50–400 mg	Oral	Daily	4.50–35.25
Posaconazole	600–800 mg suspension 300 mg daily tablet 300 mg IV	Oral	Daily	175 636

[a] Average wholesale price, on average.

GI, gastrointestinal; QID, four times daily; TID, three times daily.

Identification of new antifungal compounds has been challenging. One significant barrier is that both mammalian cells and fungal cells are eukaryotes and share many similar biochemical processes, unlike bacterial cells, which are prokaryotes. Traditionally, the drug discovery process depended on the ability to detect compounds (either natural products or synthetic compounds) that selectively inhibit or destroy fungal cells. This process is accomplished by either or both of two approaches: (a) the evaluation of existing compounds (natural or synthetic) for potentially useful antifungal activity and (b) the design and synthesis of new compounds that selectively block fungal targets. Recent advances in genomic sequencing of C. albicans, C. glabrata, Aspergillus fumigatus, Rhizopus oryzae (delmar), and C. neoformans have facilitated the search for new targets. Other less conventional drug discovery approaches include targeting known traditional virulence factors (e.g., adhesions and secreted enzymes). This approach is based on the principle that killing of the microbe need not occur for an anti-infective agent to be efficacious. Promising lead compounds include nikkomycins, sordarins, lytic peptides, hydroxypyridones, and cathelicidins.[32–35]

SUPERFICIAL AND CUTANEOUS MYCOSES

Tinea Pedis: Treatment

CASE 78-1

QUESTION 1: C.W., a 28-year-old male construction worker, is evaluated for a chronic case of “athlete’s foot.” He wears boots all day at work and notes intense itching of both feet throughout the day. He has been using tolnaftate powder for 1 week with no real therapeutic benefit. On examination, the web spaces between all the toes are white, macerated, and cracked. A few vesicles are also present over the dorsum of the foot at the base of the toes. Scrapings of the lesions examined as a potassium hydroxide (KOH) preparation reveal branching, filamentous hyphae compatible with a dermatophyte infection. The diagnosis of athlete's foot is made. What therapeutic options are available for C.W.?

Selection of antifungal therapy should be based on the extent and type of infection.

Superficial or cutaneous infections should initially be approached topically. Any follicular, nail, or widespread (>20% of body surface area) infection should be treated systemically under medical supervision owing to poor penetration of topical applications. Topical antifungals have been reviewed as a class by the FDA advisory review panel on over-the-counter (OTC) antimicrobial drug products and on an individual basis as newer products have been released. To receive a class I recommendation, each agent (or combination) must have been tested in well-designed clinical trials that show that the drug is microbiologically and clinically effective against dermatophytosis or candidiasis with insignificant toxicity (irritation). Class I agents are listed in Table 78-3. Class II agents (camphor, candicidin, coal tar, menthol, phenolates, resorcinol, tannic acid, thymol, and tolindate) are considered to have higher risk–benefit ratios associated with their pharmacotherapy. Class III agents (benzoic acid, borates, caprylic acid, oxyquinolines, iodines, propionic acid, salicylates, triacetin, and gentian violet) lack adequate scientific data to determine efficacy. Topical therapy with any class I agent applied twice daily to the affected area for 2 to 6 weeks should be adequate. Therapy should be titrated to response.

C.W. could continue tolnaftate powder for 2 to 6 weeks or switch to an antifungal cream or lotion (e.g., miconazole and terbinafine), and these products should be applied to the web spaces between all the affected toes twice daily. C.W. should also be careful to use nonocclusive footwear (e.g., cotton rather than synthetic fiber socks and leather rather than vinyl boots). Application of an absorbent or antifungal powder to his footwear would also be helpful (see Chapter 39, Dermatotherapy and Drug-Induced Skin Disorders).

Tinea Unguium (Onychomycosis): Treatment

CASE 78-1, QUESTION 2: If C.W. also suffered from an infection of the toenail (onychomycosis), what additional therapy could be offered to him?

Onychomycosis is typically caused by a dermatophyte, a hyphal fungi, or Candida.

Nail scrapings and culture should be performed to help plan initial therapy. Once culture results are known, therapy can be initiated with either terbinafine 250 mg/day or itraconazole 200 mg/day for 6 (fingernail) to 12 (toenail) weeks. In some cases, however, successful therapy of tinea unguium can require 3 to 6 months for fingernails and 6 to 12 months for toenails. Therapy should be considered successful when several millimeters of healthy nail have emerged from the nailfold to the margin of infected nail or when a 25% reduction in the size of the infected site has been achieved.

For dermatophyte nail or paronychial infections, griseofulvin therapy could be used if an azole or allylamine is contraindicated. Griseofulvin (microsized or ultramicrosized) administered orally at 10 mg/kg/day and titrated to response should be effective.[25] Owing to the large doses given for prolonged periods, C.W. should be monitored closely at each prescription refill for signs and symptoms of adverse reactions. The most common adverse events associated with terbinafine or itraconazole are headache, rash, and GI distress. Griseofulvin is more toxic, often causing hypersensitivity (urticaria, angioedema, and type II hypersensitivity reactions), photosensitivity dermatitis, GI distress, and neurologic complications (headache, paresthesias, and altered sensorium).[25]

Antimycotic pulse therapy is a novel approach to the treatment of onychomycosis. An FDA-approved alternative to daily therapy can now include a course of itraconazole 200 mg twice daily for 1 week in two consecutive months for fingernail infections. Double-blind, placebo-controlled trials revealed that this regimen was associated with a 77% clinical response and 73% mycologic response.[36] Overall responses and toxicity to therapy were more desirable with pulse regimens than with traditional regimens. Comparative studies demonstrate promising results for itraconazole pulse therapy for toenail infections[37] and fluconazole pulse therapy administered as a 150- to 450-mg dose once weekly for up to 12 months for mild disease.[38,39] Relapse rates after pulse (intermittent) terbinafine for 4 months have been frequent, and longer courses of therapy are under study to enhance long-term efficacy.[40] Longer courses of therapy are being evaluated.

Removal of the nail as the sole therapy is not recommended because of the high relapse rate without concomitant systemic therapy. Likewise, IV antifungals are not indicated.

CASE 78-1, QUESTION 3: Describe the role of corticosteroids, antibacterials, or other additives to the antimycotic regimen in C.W.

Many patients with superficial, cutaneous, or nail fungal infections will have local inflammation and secondary bacterial infections. Inflammation is primarily a type IV hypersensitivity reaction. Topical corticosteroids in conjunction with antifungals can relieve itching and erythema secondary to inflammation. Bacterial (Proteus or Pseudomonas species) superinfection can also occur in these inflamed or macerated areas requiring concomitant topical antibacterial therapy. Pharmaceutical manufacturers of OTC preparations often combine a drying agent or astringent (e.g., alcohol, starch, talc, and camphor) to their preparations to increase desquamation of the stratum corneum. Hyperhidrosis also can be relieved by these pharmaceutical additions. Such combination treatments should not be used routinely, however, because they increase the risk of toxicity and do not increase efficacy. If required for symptomatic relief, they should be used only for the initial days of treatment.

The affected web spaces between C.W.'s toes are macerated and cracked, and vesicles are present at the base of his toes. A topical corticosteroid cream will probably facilitate the healing process and make him more comfortable during the first few days of antifungal therapy. The selection of topical corticosteroid formulations is presented in Chapter 39, Dermatotherapy and Drug-Induced Skin Disorders.

SUBCUTANEOUS MYCOSES

Sporotrichosis

TREATMENT OPTIONS

CASE 78-2

QUESTION 1: O.M., a 62-year-old man, has had a painless, slowly enlarging ulcer on his left hand for the past 4 months. He is an avid gardener but can identify no antecedent local trauma. The primary lesion began as a red papule that slowly enlarged and then ulcerated. At the same time that the ulcer developed, O.M. also noted painless, red nodules that spread proximally up his arm. He denies any chills, fever, weight loss, or cough. The ulcer has slowly enlarged despite the daily application of a povidone iodine ointment and 2 weeks of cephalexin treatment. On physical examination, O.M. is afebrile. A 1.5 cm^2 ulcer is present on the dorsum of the left hand. Extending proximally from the ulcer are a palpable cord and multiple nontender, erythematous nodules distributed linearly up the forearm, elbow, arm, and axilla. A culture of this ulcer obtained 4 weeks ago is now growing S. schenckii. What is the recommended therapy for O.M.?

S. schenckii is the dimorphic fungi found in the soil and on many plants. Infection is usually secondary to inoculation into the skin from a thorn or sharp plant matter. S. schenckii infection most commonly causes lymphocutaneous disease (Fig. 78-1) as illustrated by this case. Rarely, extracutaneous disease may occur and usually involves the lungs, bones, or joints.

HEAT TREATMENT

In the 1930s and 1940s, local heat was applied to very mild plaque or lymphocutaneous disease. Germination rates of this dimorphic fungus can actually be decreased by increased temperature, and heat therapy 1 hour/day for 3 months is effective in 90% of patients with plaques (very mild disease).[41] Heat treatment could be particularly useful in pregnant patients when pharmacotherapy may be contraindicated.

ITRACONAZOLE

Itraconazole is more active in vitro against S. schenckii than other imidazoles or saturated solution of potassium iodide. Saturated solution of potassium iodide is seldom used for therapy secondary to treatment-limiting toxicity. Cure rates for sporotrichosis cutaneous and lymphocutaneous disease are greater than 90% with itraconazole 100 to 200 mg/day for 3 to 6 months. For extracutaneous disease, higher dosages of itraconazole (200 mg twice a day [BID]) for 1 to 2 years achieve response rates of 81%, but relapse frequently occurs (27%) after therapy is stopped.[41,42] Itraconazole is well tolerated in these patients. Patients with extracutaneous disease who are unable to tolerate the higher itraconazole dosages or whose disease continues to progress should be treated with AmB or a lipid-based amphotericin product. A total dose of 2.0 to 2.5 g is most often recommended if conventional AmB is used. Although voriconazole, posaconazole, and ravuconazole demonstrate in vitro activity against S. schenckii (albeit less than itraconazole), their role in the treatment of sporotrichosis has not been defined.[43] Neither ketoconazole nor fluconazole is effective in the treatment of sporotrichosis.

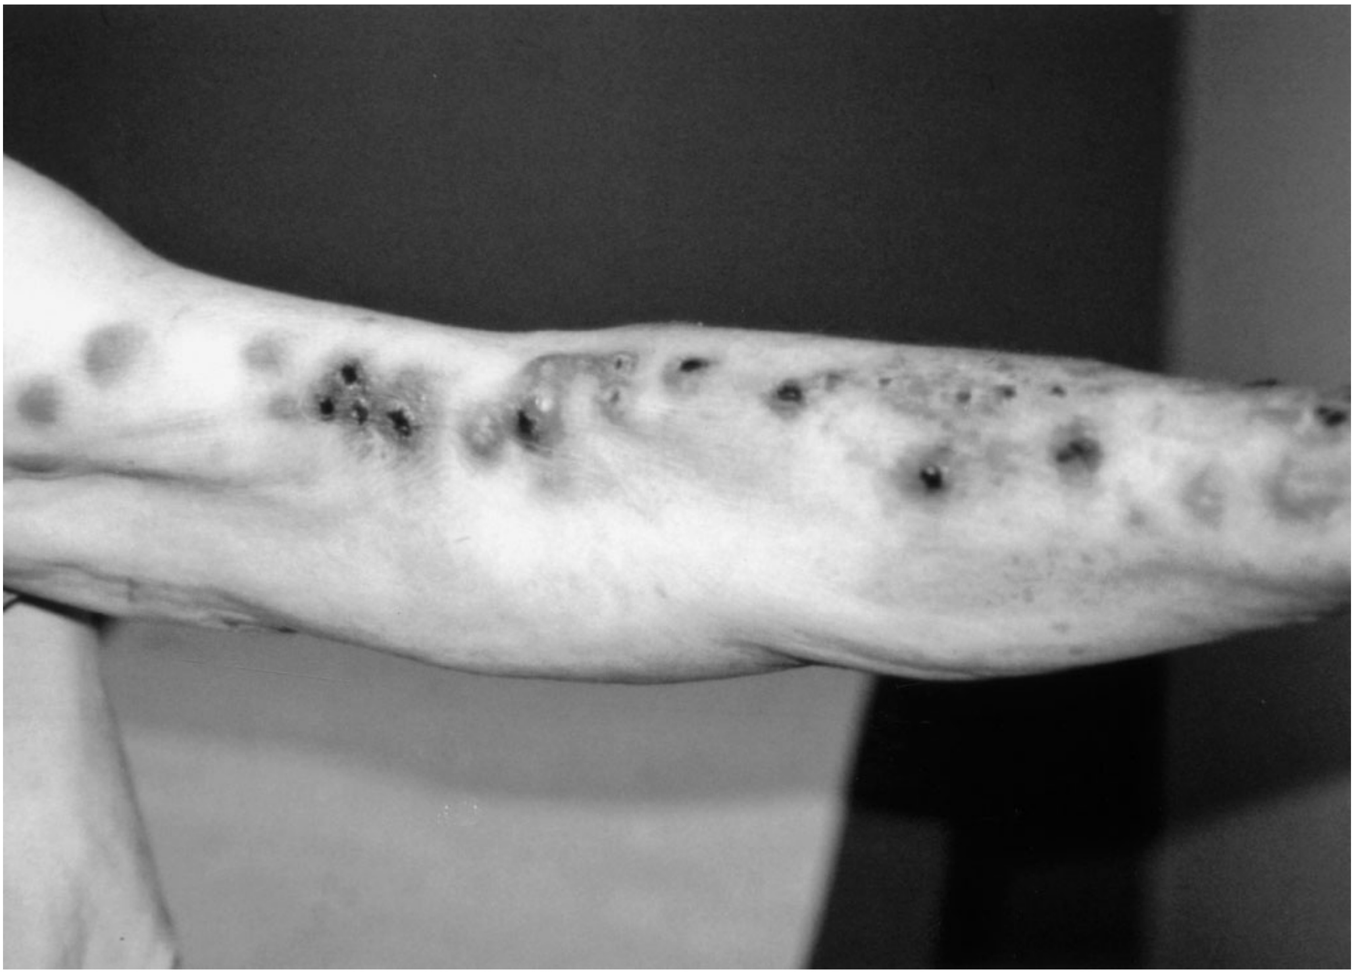

Figure 78-1 Lymphocutaneous sporotrichosis.

TERBINAFINE

Terbinafine has a good in vitro activity against S. schenckii and has been used clinically with some success.[44] An unpublished clinical trial comparing 250 or 500 mg BID for 3 months for lymphocutaneous disease appeared clinically equivalent to itraconazole. Adverse reactions include GI distress (dysgeusia, dyspepsia, and diarrhea), skin rash, and weight gain.

Therefore, in the case of lymphocutaneous disease, itraconazole 100 mg/day for a minimum of 3 months is the treatment of choice. If significant improvement is not observed in the first 6 weeks, the itraconazole dosage should be increased to 200 mg/day and continued for 6 months or until both the ulcer and lymphangitis have resolved. Most patients will respond to this dosage, but an occasional patient may require dosages of 300 or 400 mg/day.

Itraconazole Dosing

CASE 78-2, QUESTION 2: What instructions should O.M. receive for taking his antifungal agent?

The peak serum concentrations of itraconazole capsules are ninefold higher when the drug is taken with food (0.18 mcg/mL with food vs. 0.02 mcg/mL in fasting subjects).[45] The influence of food on absorption appears to be dependent on food type. High-carbohydrate meals decrease the absorption of itraconazole, and high-lipid-content meals increase itraconazole absorption.[46] Patients who have difficulty eating (e.g., patients with AIDS and those with cancer receiving antineoplastic therapy) or with hypochlorhydria may not absorb a sufficient amount from the capsule to achieve therapeutic plasma concentrations after a typical oral dose.[47] Although itraconazole manifests nonlinear serum pharmacokinetics (i.e., administering the total dose in two divided doses is associated with higher peak serum concentrations than a single larger dose), there is no clinical benefit in splitting the dose. Therefore, O.M. could be instructed to take his itraconazole capsule with his highest-fat-content meal of the day or itraconazole solution could be substituted to improve absorption.

Itraconazole oral solution is a cyclodextrin formulation that has 55% bioavailability in a fed patient; this increases in a fasting patient (Table 78-5). Furthermore, bioavailability of this formulation is not affected by level of gastric acidity. Average serum concentration in a cohort of patients with advanced HIV infection was 2.7 mcg/mL after a 28-day twice-daily dosing regimen.[48] O.M. should take his itraconazole solution on an empty stomach BID if this formulation is selected.

CASE 78-2, QUESTION 3: How would instructions for taking itraconazole capsules be modified if O.M. were achlorhydric as a result of medications or AIDS gastropathy? Should azole serum concentrations be monitored for an assessment of efficacy?

Itraconazole capsules, as with ketoconazole, require an acidic environment for dissolution and absorption. Thus, patients who are achlorhydric, as a result of medications, surgery, or underlying disease (e.g., AIDS gastropathy), may not absorb itraconazole capsules adequately.[47,49] The use of ketoconazole in achlorhydric patients has historically required concomitant administration of 4 mL, 0.2 N hydrochloric acid aqueous solution. Etching of tooth enamel by the acid can occur; thus, other alternatives have been explored. The administration of ketoconazole and itraconazole with a low pH liquid (e.g., 8–16 fluid ounces of a carbonated cola beverage or orange juice) improves absorption in 65.2% of healthy patients who are achlorhydric or taking H_2-blockers.[49] Refer to Azole–Drug Interactions section for more detailed information on problematic therapeutic combinations.

Voriconazole does not require an acidic environment for adequate oral absorption, but voriconazole should be administered 1 hour before or after meals because high-fat meals may reduce voriconazole serum concentrations.[50] In contrast, posaconazole plasma concentrations are fourfold higher after administration with food or a high-fat nutritional supplement. A newer formulation of posaconazole, which releases the drug in the pH-dependent manner in the duodenum, is not dependent on low gastric pH for dissolution and does not require administration with food to achieve therapeutic levels.[51–53] Isavuconazole is unique among triazole antifungals because it is administered IV or orally as a prodrug (isavuconazonium sulfate), which is rapidly cleaved by plasma esterases to the active antifungal, isavuconazole. Absorption of the prodrug is relatively complete (>90% bioavailability) and does not require low gastric pH or coadministration with food. IV isavuconazonium is water-soluble and, unlike voriconazole or posaconazole parenteral formulations, is not solubilized in hydroxypropyl-β-cyclodextrin.

Because serum ketoconazole, itraconazole, and voriconazole concentrations less than 0.25 to 1.0 mcg/mL have been associated with an increased risk of treatment failure and increased mortality in neutropenic patients, therapeutic drug monitoring is justified in patients in whom therapy is failing or suspected risk factors for low blood levels (i.e., poor gut function, drug interactions, and pediatric patients) or, in the case of voriconazole, suspected CNS toxicity, which is more frequent in patients with trough levels exceeding 5.5 mcg/mL.[54] Similarly, posaconazole serum concentrations less than 0.7 mcg/mL have been associated with an increased risk of breakthrough infection during prophylaxis, and trough or random levels approaching 1.5 mcg/mL have been associated with improved probability of treatment response in documented invasive aspergillosis.[54] Serum antimycotic concentrations may be more easily monitored in the future because assays, potentially performed at the point of care (patient bedside or clinic), become available, and correlations between concentration and efficacy or toxicity are more clearly established.[55]

SYSTEMIC MYCOSES

Candida Infection

CASE 78-3

QUESTION 1: L.K., a 21-year-old, 5-foot 8-inch, 170-pound, otherwise healthy man, was admitted to the hospital 16 days ago after a gunshot wound to the abdomen. He has undergone three exploratory laparotomies with repair and resection of damaged small intestine. He was placed on TPN to allow his bowel to rest and received stress doses of methylprednisolone Day 6 in hospital. Three days ago, he exhibited a fever of 39.1°C and chills; his blood pressure of 100/70 mm Hg had dropped more than 30 mm Hg (systolic). Vancomycin and meropenem were promptly begun after obtaining blood cultures. Despite 3 days of antibiotics, he remains febrile. His physical examination reveals a Hickman catheter in the right subclavian vein that is functioning normally; no inflammatory changes are evident at the exit site. A single erythematous nodule about 0.5 cm wide is noted near the left wrist. The funduscopic examination of both eyes is normal. A chest radiograph is also normal. The white blood cell (WBC) count is currently 10,950 cells/μL, and renal function is normal. What subjective and objective data in this case suggest a possible Candida infection?

EPIDEMIOLOGY

Although it is possible that L.K. might be infected with bacterial pathogens not susceptible to vancomycin and meropenem, the possibility of a candidal infection should be considered. Candida species are the most common nosocomial fungal pathogens. Candida species were responsible for 72.2% of mycoses in hospitalized cases, and C. albicans accounted for 55% of these cases in the Centers for Disease Control, National Nosocomial Infections Surveillance System. Attributable mortality associated with disseminated candidiasis from all species is 38% and it is ~12% for extremely low-birth-weight neonates.[56] These statistics may underestimate the true occurrence because systemic candidiasis is difficult to diagnose. To reinforce this point, the diagnosis of systemic candidal infection is made in 30% to 50% of neutropenic patients with hematologic malignancies at postmortem.[57] Therefore, the morbidity for systemic candidiasis may be even higher because of the limited ability to diagnose systemic disease.

CHARACTERISTICS

The diagnosis and monitoring of therapeutic outcomes for systemic candidal infection are difficult because the characteristics of systemic candidal infection are subtle. Salient clinical features include constitutional symptoms (e.g., fever, chills, and hypotension) and evidence of end-organ dissemination, such as nodular erythematous skin lesions, endophthalmitis, liver abscess, and spleen abscess. In addition, 50% of patients or fewer will have a single positive Candida blood culture. The Mycoses Study Group utilizes a single positive culture from a sterile body site and hypotension (systolic blood pressure [SBP] <100 mm Hg or a SBP decrease >30 mm Hg) or abnormal temperature (<35.5°C or >38.6°C on one occasion or >37.8°C on two separate occasions more than 4 hours apart), or inflammation at an infected site as diagnostic criteria.

RISK FACTORS

Risk factors for candidemia include central venous catheters, broad-spectrum antibiotic use, extensive surgical procedures, Candida colonization, TPN, pancreatitis, neutropenia or neutrophil dysfunction, and immunosuppression (e.g., premature infants, burn patients, patients with mannose-binding lectin deficiency, and patients with AIDS).[58]

L.K. has chills, a temperature of 39.1°C, and is hypotensive. He is probably immunosuppressed as a result of multiple surgical procedures and receipt of corticosteroids. His Hickman catheter is a possible portal of entry, and his broad-spectrum antibiotic therapy with vancomycin and meropenem should be adequate for most bacterial pathogens. Because L.K. still has manifestations of an infection despite 3 days of antibiotics, additional diagnostic studies are warranted.

DIAGNOSTIC TESTS

CASE 78-3, QUESTION 2: What diagnostic tests could be ordered for L.K. to evaluate a possible fungal infection?

The diagnosis of fungal infection may be made with varying levels of certainty. Sometimes, the diagnosis is absolutely certain, such as the isolation of a pathogenic fungus from a clinical specimen in an immunocompromised patient. Such a finding is referred to as a definitive or microbiologically confirmed diagnosis. At other times, only a high probability of infection can be determined, that is, a presumptive diagnosis. To illustrate this, a patient with a chest radiograph showing nodular lesions and a high complement fixation (CF) antibody against H. capsulatum would have a presumptive diagnosis of histoplasmosis. This finding may be as certain a diagnosis as is possible without performing a more invasive procedure to obtain lung tissue. In this event, a trial of drug therapy can be undertaken on the presumptive diagnosis alone. A diverse spectrum of tests is available for clinicians to diagnose and monitor therapeutic responses.

Direct Examination

Direct examination of the specimen is often useful in diagnosing fungal infection. Traditionally, the specimen is treated with 10% KOH to digest the cells and debris, resulting in clear visualization of the hyphae or yeast. Treatment of cerebrospinal fluid (CSF) specimens with KOH is not necessary because this fluid is naturally clear. India ink can be added to CSF to increase contrast and outline the organisms. Calcofluor white, a fluorescent fabric brightener that binds to fungi and fluoresces brilliantly when viewed under the ultraviolet microscope, can also be used to assist in the recognition of fungal elements.

Histologic examination of biopsy specimens is an important tool for diagnosing and monitoring fungal infection, but identifying the exact fungus may be difficult. This is because only the tissue phase can be observed, and the fungal organisms in the specimen may be few. Because recognizing a fungus in hematoxylin-stained or eosinstained sections may be difficult, a number of special stains have been developed.[58] Periodic acid–Schiff staining binds linked sugar groups in the fungal cell wall. This intense magenta staining makes visualization of the fungal form easier. Likewise, several silver precipitation stains (e.g., Gomori methenamine silver) rely on the presence of a charged fungal surface to reduce oxidized silver to metallic silver. This process coats the fungus with a black layer, again outlining the form.[59] The mucicarmine stain imparts a deep red color to complex polysaccharides, such as mucin, which can stain the thick capsule of C. neoformans. Because no other yeast has a positive mucicarmine stain, the definitive diagnosis of cryptococcosis can be made.[60] The size of the organism, manner of budding, and the presence or absence of septae all assist in the diagnosis.

Monoclonal antibodies against many fungi are now available. Immunohistochemical procedures using these sera on biopsy specimens

allow for the identification of a number of fungal pathogens.[60] Reagents for in situ oligonucleotide probe hybridization to detect fungi in tissue are being developed and will also be extremely helpful.[61]

Culture

The most definitive method for diagnosing or monitoring a fungal infection is using culture. Specimens should be inoculated onto several different types of fungal media, some of which contain antibiotics to inhibit bacterial overgrowth. Swab specimens have a very low yield, especially for hyphal fungi, and should be avoided in follow-up cultures. Yeast may grow rapidly and be isolated within 24 to 48 hours, but many fungi grow slowly, and 4 to 6 weeks of incubation may be necessary to isolate and identify the organism. After growth, yeasts are usually recognized by their patterns of metabolic activity on a variety of substrates, whereas mycelial organisms may produce characteristic spores and fruiting bodies that are used for identification. Occasionally, a mycelial organism will be slow in producing recognizable spores, and immunologic testing for a characteristic isoantigen may be used for identification. A peptide nucleic acid fluorescence in situ hybridization test more rapidly identifies C. albicans from blood-culture bottles.[62] It is unclear how cost-effective this test will be compared with traditional germ-tube testing.

Antigen Detection

Fungi synthesize polysaccharides that cannot be broken down by human enzymatic systems. These polysaccharides can accumulate within the body and can be excreted in the urine. These fungal antigens can be detected by using antibodies that specifically recognize a particular species of fungus, thereby providing a diagnosis.

The most commonly used antigen detection test is a latex agglutination test for cryptococcal antigen. This assay can be performed on serum or CSF. Antigenemia is present in 80% to 100% of patients with culture-proved cryptococcal meningitis. This test can also be used to monitor patient response to therapy by determining the end point dilution for the positive reaction and following this end point over time when the patient is treated. If treatment is successful, the titer will decline.[63,64]

Tests (quantitative polymerase chain reaction, enzyme-linked immunosorbent assay [ELISA], and latex agglutination) for other fungal antigens are also not established. Latex particle agglutination tests to detect candidal antigens are available, but their utility has not been clearly demonstrated. Assays for detecting H. capsulatum antigen in serum and urine have been reported.[65] Antigen can be detected in the blood of 50% of patients and in the urine of 80% to 90% of patients with systemic histoplasmosis. Patients with blastomycosis and paracoccidioidomycosis, however, may also have positive cross-reactions. The ELISA for the detection of Aspergillus galactomannan antigen (Section 78-8) and Candida (1–3)-β-D-glucan has reported sensitivity (63%) and specificity (96%) of two consecutive (1–3)-β-D-glucan results greater than 7 pg/mL, which is clinically useful. Using these tests can result in a shorter time to diagnosis and leads to significantly shorter time of illness compared with other diagnostic tests. β-Glucan is most valuable for its negative predictive value.[66] Considering the presence of false-positives or false-negatives, it is unknown whether these assays will improve diagnostic capability for patients at a risk for these infections. False-positives may be caused by a myriad of products (IgG, albumen, cellulose filters, or gauze bandages) with variable outcomes associated with pipercillin/tazobactam manufactured antibiotics. Increasing or decreasing values can be used to monitor clinical response to antifungal therapy.[62]

Antibody Detection

The detection of antibody can be useful for some fungal diseases, but not for others. Serologic diagnosis of systemic candidiasis is complicated because most people have anti-Candida antibodies. A rising titer is not specific for infection and may indicate only colonization. Furthermore, dissemination of Candida is most likely in people who are immunocompromised and, therefore, may not respond by producing antibody.[67] On the other hand, seropositivity can be demonstrated in more than 90% of patients with symptomatic histoplasmosis.[68] The most important serologic tests use the CF, immunodiffusion, and enzyme immunoassay (EIA) techniques. The appropriate evolution of serologic results requires an understanding of the sensitivity, specificity, and predictive value of each methodology. In general, serologic tests allow only a presumptive diagnosis of mycotic infections.

Although any of the aforementioned tests could be ordered for L.K., a direct examination of his blood and urine specimens along with an assessment of signs and symptoms of disseminated candidiasis is a reasonable first step in his evaluation. A blood specimen from L.K. should also be cultured on different fungal media. Because a candidal infection is suspected, the culture could isolate Candida within 24 to 48 hours. Cultures and histopathologic examination of a biopsy specimen of skin lesions are often helpful not only in confirming a diagnosis of disseminated candidal infection, but also in monitoring response to therapy. The other fungal tests previously described need not be ordered immediately and should await the results from the direct examination and culture.

NECESSITY OF TREATMENT

CASE 78-3, QUESTION 3: The clinical laboratory reports that a single blood culture obtained 2 days ago is growing Candida species. Why is therapy necessary in L.K. with only a single positive blood culture?

Case–control studies of candidemia report an 85.6% mortality rate in untreated patients compared with a 41.8% mortality rate in patients who received early treatment. Isolation of Candida from a patient's bloodstream requires the initiation of immediate antifungal therapy. Delays in therapy are associated with a significant increase in mortality. In fact, delaying therapy 24 hours from the time a blood culture is positive or failure to follow IDSA treatment guidelines increases mortality nearly 50%.[69–71] Elimination of risk factors may improve the clinical outcome of candidemia, and the removal of central venous catheters reduces morbidity and mortality.[72,73] Although discontinuation of a centrally inserted catheter may complicate drug administration, it still should be removed. L.K.'s other risk factors (e.g., broad-spectrum antibacterials) are perhaps of even greater importance.

TREATMENT OPTIONS AND COMBINATION THERAPY

CASE 78-3, QUESTION 4: What therapeutic options are available to treat candidemia? Which option would be best for L.K.?

Therapeutic options are individualized and based on the competence of a patient's host defenses. In immunocompetent patients, AmB formulations, an echinocandin, or a triazole decreases morbidity and mortality associated with this disease.[74–78] Echinocandins have been demonstrated as effective as AmB formulations in neutropenic and non-neutropenic patients; however, AmB clears the bloodstream more rapidly.[79,80] In the largest, well-controlled comparative trial, 206 non-neutropenic patients were randomly assigned to AmB 0.5 to 0.6 mg/kg/day or fluconazole 400 mg/day for 14 days. Mortality was less than 9% in both the groups with no significant difference in successful outcomes (AmB, 80%; fluconazole, 72%). Less toxicity was noted in the fluconazole group, however.[75] Therefore, fluconazole 400

---

mg/day is as effective as AmB for non-neutropenic patients infected with susceptible Candida. Candidemic (or other mycotic infections discussed in this chapter) patients who are clinically stable and have no evidence of deep-seated infection should be initiated on a triazole or an echinocandin for at least 14 days. Patients who cannot be treated with an echinocandin or an azole can be treated with AmB 0.5 to 1.0 mg/kg/day or 3 to 5 mg/kg/day of a lipid formulation of AmB. Alternatively, a comparison of micafungin (100 or 150 mg) with caspofungin revealed no difference with micafungin 100 mg and caspofungin after 10 days of therapy. However, micafungin 150 mg trended toward poorer responses.[81]

High-dose fluconazole (12 mg/kg/day) alone or in combination with AmB for a minimum of 3 days, followed by step-down therapy to fluconazole, was evaluated. Outcomes were not different between treatment groups and consistent with the previously reported success rates. Notably, the fluconazole treatment group had higher Acute Physiology and Chronic Health Evaluation (APACHE II) scores, making evaluation of the comparison difficult.[79] In contrast, in another clinical trial, the combination of AmB and flucytosine was suggested to be more effective than single-agent therapy.[82,83] An AmB-containing regimen may be more effective in patients with APACHE II scores between 10 and 22.[79]

L.K. could be treated with an echinocandin, with the total duration based on clinical response and resolution of positive cultures (see Case 78-3, Question 6). Therapy typically should be continued for 14 days post–last positive blood culture. Some clinicians check cultures daily to assess this end point. Efficacy should be monitored using patient-specific signs and symptoms of candidemia. Combination therapy can be considered in those patients who are not responding clinically. More importantly, a complete examination for focal sites of infection (septic thrombi or intra-abdominal abscess) should take place.

CASE 78-3, QUESTION 5: This fungal species has now been identified as C. non-albicans. How does this affect the therapeutic options for L.K.?

Historically, the isolation of a non-albicans Candida from blood has resulted in a therapeutic dilemma caused by common in vitro resistance, which has been associated with poor clinical outcomes in animal models and uncontrolled case reports. Intrinsic resistance (i.e., Candida lusitaniae to AmB, C. parapsilosis to echinocandins, and Candida krusei to fluconazole) or acquired resistance (C. tropicalis or glabrata against fluconazole) has been reported.[76,82,83] Acquired in vitro fluconazole drug resistance is probably associated with altered fungal cell membrane permeability, antifungal efflux pumps, and changes in CYP450 enzymes. In observational studies, fluconazole resistance in vitro has been 9%.[76,82,83] A large, multicenter study of 232 non-neutropenic patients was unable, however, to demonstrate a relationship between yeast MIC and patient outcome.[76] An inability to demonstrate a relationship is probably a result of a limited understanding or inadequate management of risk factors for infection. For example, the removal of a colonized IV catheter is probably a more important predictor of outcome than the MIC of the isolated yeast. A disturbing increase in acquired C. glabrata resistance to the echinocandins via a FKS gene, first reported in 2008, should be suspected in echinocandin treatment failures.[27,84]

Therefore, the true rate of acquired clinical resistance to azoles and ultimate failure is unknown. Vigilant monitoring and aggressive therapy of infections caused by Candida non-albicans are recommended. In patients in whom susceptibilities are available, fluconazole should be avoided when the MIC is greater than 16 mcg/mL.

AMPHOTERICIN FORMULATIONS

Dosing

CASE 78-3, QUESTION 6: How should amphotericin B formulation be dosed and administered to L.K.?

The AmB formulation dose and duration of therapy should be individualized based on the severity of infection and immunocompetence of the patient. Once the patient is stable, therapy should be changed to one of the applicable regimens discussed previously. The dose of AmB formulations should be based on lean body mass. Owing to the difficulty in measuring lean body mass, many clinicians, however, use ideal body weight. Tissues that contain large numbers of macrophages sequester significant amounts of AmB (liver, 17.5%–40.3%; spleen, 0.7%–15.6%; kidney, 0.6%–4.1%; and lung, 0.4%–13%), but it does not distribute well into adipose tissue (<1.0%).[77,78] In fact, AmB formulations bound to cholesterol have been shown to bind to clathrin-coated pits (low-density lipoprotein receptors or receptors of endocytosis) on cells, facilitating intracellular incorporation and possibly reducing renal toxicity.[85] Because L.K. is 5-feet and 8-inches tall and not obese, his ideal body weight should be about 70 kg. Therefore, generic AmB 35 mg/day (0.5 mg/kg) should be initiated because L.K. is not clinically stable and may require increased doses. Half of the full dose should be given on the first day of therapy and the full dose given on subsequent days. In more seriously ill patients, the full dose of generic AmB can be initiated immediately. Although the optimal dosing regimen to initiate generic AmB is not well established, most clinicians gradually titrate the dose upward to minimize infusion-related reactions. Peak AmB serum concentrations achieved after parenteral administration are a function of dose, frequency of dosing, and the rate of infusion. When the AmB total dose is less than 50 mg, the serum concentration is directly proportional to the dose; doses greater than 50 mg are associated with a plateau in serum concentrations. After administration, AmB undergoes biphasic elimination: Peak serum concentrations drop rapidly (initial $t_{1/2}$, 24–48 hours), but low concentrations (0.5–1.0 mcg/mL) are detectable for up to 2 weeks (terminal $t_{1/2}$ 15 days).[86] The long terminal elimination half-life has been used as a justification for the common practice of less frequent AmB dosing, in which twice the daily dose is given every other day. Every-other-day regimens have not been carefully evaluated but are rationalized based on the potential for reduced nephrotoxicity. Administration of generic AmB 0.5 mg/kg/day or 1.0 mg/kg every other day results in trough AmB concentrations with sufficient postdose antifungal effects that inhibit the common pathogenic fungi.[87] Once L.K.'s clinical status has improved, the potential for renal toxicity could outweigh the concerns of potential reduced efficacy, and implementation of AmB every-other-day therapy should be considered.

Infusion Reactions

CASE 78-3, QUESTION 7: L.K. has no complaints except for fevers and shaking chills that occur during his 6- to 8-hour AmB infusion for the past 3 days. He has been receiving acetaminophen 650 mg 30 minutes before AmB infusion, but he has refused today's AmB dose. What measures can be taken to minimize these infusion-related reactions?

Adverse reactions, which are common with AmB formulation administration, are best classified as infusion-related, dose-related, or idiosyncratic reactions. Infusion-related reactions include an acute symptom complex of fever, chills, nausea, vomiting, headache, hypotension, and thrombophlebitis. Dose-related reactions also can be acute (e.g., cardiac arrhythmias) or chronic (e.g., renal

---

dysfunction with secondary electrolyte imbalances and anemia). Premedication to prevent AmB formulation, infusion-related reactions, and a test dose of AmB formulations are not needed for L.K. Most practices of premedicating are performed out of ritual rather than predicated on a scientific study.[88] Test dosing with 1 mg before the first dose is not currently used because of the immeasurably low incidence of anaphylactoid reactions. Until clinical trials clarify the risk–benefit ratio of premedications, concomitant therapy should be restricted to acetaminophen for fever or headache and heparin to prevent thrombophlebitis when possible.

Many infusion-related reactions are mediated by AmB-induced cytokine (interleukin-1β, tumor necrosis factor, and prostaglandin E_2) expression by mononuclear cells.[89,90] Hydrocortisone is extremely effective in suppressing cytokine expression,[89] and it also blunts the fever and chills associated with AmB formulations.[91] Hydrocortisone, however, does not reduce the frequency of chronic dose-related toxicity such as renal insufficiency, and corticosteroid-induced immunosuppression could decrease AmB fungicidal activity.[92] Nonsteroidal anti-inflammatory drugs (NSAIDs) also prevent fever, most likely by the suppression of prostaglandin E_2 expression.[93] NSAIDs, however, cannot be recommended for routine use because of their potential for additive nephrotoxicity when used with AmB formulations.

The mild-to-moderate elevations in temperature and the other infusion-related symptoms usually subside when the infusion is completed, and tolerance to these effects develops over 3 to 5 days. L.K. initially should be counseled that these reactions will abate over the next few days without intervention. If assessment of the reactions suggests the need for more aggressive premedication, a short course of hydrocortisone 0.7 mg/kg prior to AmB or added to the infusion bag should be initiated.[91] Meperidine 25 to 50 mg by rapid IV infusion reduces AmB-induced rigors and can be repeated every 15 minutes as required while monitoring for signs and symptoms of opiate toxicity. Administration of an average meperidine dose of 45 mg has been found to resolve chills 3 times faster than placebo.[94]

Fast generic AmB infusion rates (< normal 4–6 hours) are associated with the earlier onset of infusion-related reactions, but not with more severe infusion reactions.[95,96] Many patients prefer rapid infusions (1–2 hours) because the infusion-related reactions abate quickly on the completion of the AmB infusion. Electrocardiographic evaluations of 1-hour infusions indicate that this rate of polyene infusion is safe at currently recommended doses in patients without renal or heart disease. Rapid infusions are not safe in all patients, however, because cardiac arrhythmias appear to be dose- and infusion rate–related. If infused too rapidly, high serum concentrations of AmB can precipitate severe cardiac adverse events. Arrhythmias have been reported most often in patients who are anuric or who have previous cardiac disease.[97] Continuous infusion is not recommended based on the pharmacodynamics of this agent and the concentration dependence of activity.

Nephrotoxicity

CASE 78-3, QUESTION 8: On Day 4 of therapy with AmB, L.K.'s serum creatinine (SCr) and blood urea nitrogen (BUN) are 2.3 mg/dL (SI units, 203.32 μmol/L) and 42 mg/dL (SI units, 14.99 mmol/L), respectively. How could AmB exacerbate L.K.'s renal dysfunction and how could it be prevented from worsening?

Renal dysfunction is the adverse event that most often limits treatment with AmB formulations. The renal toxicity results from AmB-mediated damage to renal tubules, which causes electrolyte wasting and disrupts the tubuloglomerular feedback mechanism. The clinical manifestations of AmB-induced renal damage include azotemia, renal tubular acidosis, hypokalemia, and hypomagnesemia.[88] The renal insult along with infusion-related reactions appears less severe in patients with higher serum cholesterol. This may be associated with the clathrin binding discussed earlier. Generally, AmB-related renal toxicity is reversible within 2 weeks after therapy has been discontinued. Administration of normal saline (250 mL) immediately before AmB administration reduces the risk for AmB-induced nephrotoxicity[98] and should be initiated before L.K.'s next dose. AmB formulations should not be admixed with normal saline, however, because sodium causes AmB to precipitate into an inactive particulate in IV admixture formulations.[99] Other nephrotoxins should be avoided (especially diuretics), and patients with already-compromised renal function should be closely monitored and alternate therapy should be considered.[99] Hypokalemia and hypomagnesemia should also be monitored closely. These measures to prevent further renal deterioration should be implemented, and the AmB therapy continued cautiously in this patient with systemic candidiasis. Anemia, associated with decreased renal production of erythropoietin, should resolve after AmB is discontinued and need not be treated.[100]

CASE 78-3, QUESTION 9: L.K. has exhibited significant renal dysfunction resulting from acute tubular necrosis. How should his dose of systemic antifungal drugs be altered?

Renal elimination of the antimycotics varies tremendously. For systemically administered AmB, only 5% to 10% of unchanged drug is eliminated in urine and bile during the first 24 hours,[88] and no evidence indicates that it is metabolized to a significant extent. Therefore, no substantial dosage adjustment is required for patients with chronic renal or hepatic failure. Although many clinicians will withhold AmB doses if acute renal dysfunction develops during therapy, concerns of drug-induced nephrotoxicity in L.K. must be balanced against the high likelihood of mortality in untreated patients with deep-seated infections.[55,56] Alternative systemic antifungal therapy (i.e., azoles or echinocandins) that is less nephrotoxic should also be considered. Dosing recommendations for echinocandins are unchanged in renal dysfunction or liver dysfunction, except for caspofungin. For patients with moderate hepatic insufficiency (Child–Turcotte–Pugh score 7–9), a change in the maintenance dose of caspofungin to 35 mg/day is recommended, even though the higher exposures expected with the standard dose are generally well tolerated. No data are available for caspofungin used in severe hepatic impairment, and a further dosage reduction should be considered.

Ketoconazole and itraconazole undergo first-pass metabolism and have a biphasic dose-dependent elimination.[45,46] These agents are extensively metabolized and excreted in the bile; small amounts of unchanged drug are excreted in the urine; therefore, no need exists to adjust dosages in patients with renal dysfunction or in patients undergoing dialysis.[101] Voriconazole is extensively metabolized by cytochrome P450 2C19 and to a lesser extend CYP3A4 to inactive metabolites excreted in the urine. However, the IV formulations of voriconazole and posaconazole are solubilized in sulfobutylether-β-cyclodextrin, which is eliminated via the kidneys. Accumulation of the cyclodextrin vehicle is associated with a theoretical potential for renal toxicity not reported to date in patients including those with renal impairment.[102,103] Therefore, oral therapy (or possibly isavuconazole) may be preferred in patients who require a broad-spectrum triazole but have impaired renal function. Fluconazole, unlike ketoconazole and itraconazole, is not extensively metabolized. More than 90% of a fluconazole dose is excreted in urine, of which about 80% is measured as unchanged drug and about 20% as metabolites.[104]

Because fluconazole is excreted primarily unchanged in the urine, dosages should be adjusted in patients with renal insufficiency (Table 78-5).[23,24,45–48,88,101–111] Fluconazole or voriconazole may be reasonable alternatives in L.K., but the dosage must be adjusted for renal function based on published nomograms.[105]

CASE 78-3, QUESTION 10: What is the role of an AmB formulated with a lipid?

Lipid formulations of AmB have been approved by the FDA for patients who are unable to tolerate generic AmB (Table 78-6). In addition, the admixture of AmB in 10% or 20% lipid emulsion has been used for treating systemic mycotic infections. The lipid carriers differ tremendously for each of the amphotericin formulations. The liposomal formulation is a spherical carrier that contains AmB on both the inside and outside of the vesicle. Imagine the lipid complex as a snowflake shape and the colloidal dispersion shaped like a Frisbee with AmB bound to the structure. The differences in structure appear to have no effect on therapeutic outcome but exhibit markedly different pharmacokinetics and rates of AMB release in vivo, which may account for difference in the rates of adverse effects observed with each formulation[112] AmB admixture with a lipid emulsion cannot be recommended until a stable formulation can be established.[113] Yet, similar in concept, some clinicians administer AmB formulations with breakfast (high-cholesterol meals) to simulate or enhance “lipid” coadministration, macrophage clathrin pit binding, and subsequent decreases in toxicity.

Limited data on AmB formulation comparisons are available to assist in the management of this case. A single large controlled trial has evaluated AmB lipid complex for the treatment of disseminated candidiasis. Generic AmB 0.6 to 1.0 mg/kg/day for 14 days was slightly, but not significantly, superior to the lipid complex formulation at 5 mg/kg/day for mycologic efficacy (68% vs. 63%) or survival.[114] Renal dysfunction defined as a doubling in SCr, however, was 47% with AmB and 28% with this lipid formulation. Because of the significant cost, some health-care facilities reserve lipid formulations for patients who have preexisting renal dysfunction or those who have severe adverse reactions to generic AmB. However, most centers use lipid formulations as their formulary polyene owing to patient acceptance and cost of AmB-associated renal dysfunction. Indications for the lipid formulations are further reviewed in the discussion of sections on aspergillosis, histoplasmosis, and cryptococcosis.

ANTIMYCOTIC PROPHYLAXIS

CASE 78-3, QUESTION 11: What measures could have been undertaken to prevent invasive fungal infections in L.K.?

In 2014, the National Institutes of Allergy and Infectious Diseases (NIAID)/Mycoses Study Group completed a randomized, double-blind, placebo-controlled trial of caspofungin prophylaxis followed by preemptive therapy for invasive candidiasis initiated on the basis of an antigen diagnostic test (β-D-glucan) among high-risk patients in the intensive care unit (ICU) setting.[115] The study utilized a validated risk-prediction score for invasive candidiasis that identified 18% of subjects admitted to the ICU with a predicted invasive candidiasis incidence rate of greater than 10%. Caspofungin prophylaxis was not associated with a reduction in the incidence of proven or probable invasive candidiasis or patient mortality. Therefore, prophylaxis among non-neutropenic patients at this time should be restricted to patient populations with proven benefit: post GI perforation, severe pancreatitis, liver/pancreas or small bowel transplant recipients, and extreme low-birth-weight neonates.[57]

Selective GI decontamination or systemic antimycotic pharmacotherapy can be used in high-risk, immunocompromised, or surgical patients to prevent the development of fungal infections and could have been used for L.K. In critically ill surgical patients, the risk of invasive infection, but not mortality, may be reduced by more than 50% with fluconazole prophylaxis.[116] Alternatively, a nonabsorbable antifungal such as AmB or nystatin is a possible option. Oral AmB decreases systemic candidal infections threefold to fivefold in high-risk patients.[117] Yet the problems of unreliable antifungal stool concentrations,[118] decreasing azole cost associated with the availability of generics, and poor compliance have led to preferential azole use. Azoles are also more effective in preventing oral pharyngeal candidiasis than placebo.[119,120] At the present time, no well-designed studies have compared azoles with polyene antifungals (e.g., AmB) for the prevention of oropharyngeal or systemic candidiasis.

Prophylaxis could be initiated and continued until L.K. is no longer immunocompromised. If L.K. is discharged from the hospital and treated as an outpatient, a systemic azole (imidazole or triazole) administered once daily is preferable to a polyene to improve adherence. To reemphasize, however, systemic therapy increases the risk of resistance, adverse effects, drug interactions, and potentially cost (Table 78-4). Therapeutic drug monitoring may be necessary in these patients.

Candiduria

TREATMENT

CASE 78-4

QUESTION 1: M.Y., a 24-year-old man, has been hospitalized in the surgical ICU with multiple traumatic injuries resulting from a motor vehicle accident. Shortly after admission, he underwent an exploratory laparotomy for a ruptured spleen and lacerated liver. He subsequently suffered from respiratory and renal failure. M.Y. is currently intubated and on mechanical ventilation. Since admission, he has been nutritionally supported with central hyperalimentation and has been receiving broad-spectrum antibiotics (gentamicin, ampicillin, and metronidazole). A Foley catheter is in place. Two recent urinalyses (UAs) show budding yeast, and cultures were positive for greater than 100,000 colony-forming units of C. albicans. M.Y. is currently afebrile, his funduscopic examination is normal, and no macronodular skin lesions are present. The WBC count is 8,900 cells/μL (SI units, WBC count, 8.9 × 10^9/L), and three sets of blood cultures drawn during the past 2 days are negative. How should M.Y.'s candiduria be treated?

It is difficult to differentiate among cystitis, urethritis, or systemic infection in the presence of funguria. Similarly, it is difficult to differentiate colonization from infection because candiduric patients are usually asymptomatic. Funguria cannot be used to determine the location or severity of invasion. Signs and symptoms of systemic disease should be monitored diligently until a diagnosis of colonization, cystitis, or urethritis is confirmed and the risk of dissemination is excluded.

Eradication of fungi in the urine (specifically C. albicans) should begin with the removal of the indwelling urinary catheter and alleviation of risk factors for fungal disease. If catheter removal does not clear the urine within 48 hours, pharmacotherapy should be considered. If M.Y. is scheduled for a genitourinary procedure, he should receive systemic therapy because the rate of candidemia after surgery is high (10.8%) in candiduric patients. In addition, any patient at a high risk for dissemination into the blood should be considered for treatment (e.g., patients with immunosuppression).[121]

Table 78-6

Amphotericin B Formulations

Category	Amphotericin B (Fungizone)	Amphotericin B Lipid Complex (Abelcet)	Amphotericin B Colloidal Dispersion (Amphotec)	Liposomal Amphotericin B (AmBisome)		Amphoter B in Lipid Emulsion

Bladder irrigation with AmB has been used in the past at concentrations of 150 mcg/mL, however has limited clinical utility, and is not recommended by the Infectious Diseases Society of America.[122] In two comparative studies, bladder irrigation for 5 days with AmB 50 mcg/mL was superior to fluconazole 100 mg/day as measured by microbiologic cure rates. Clinical cure rates at 2 to 4 weeks were equal—however, mortality rates were higher in the AmB-treated groups. It was suggested that AmB failures may have been associated with dissemination of yeast from the urinary tract.[123,124] Systemic antifungal therapy with flucytosine 100 to 150 mg/kg/day for 7 days[125] and azoles (fluconazole 0.6–1.4 mg/kg/day for 7 days)[126,127] also has been used in noncomparative or nonrandomized studies. Newer triazoles (voriconazole, posaconazole, and isavuconazole) or echinocandins are not recommended for the treatment of candiduria owing to their low concentrations in urine, even though some case series have suggested that clearance of positive cultures is possible on echinocandin therapy.[128]

Blastomycosis

ETIOLOGY

CASE 78-5

QUESTION 1: C.P., a 17-year-old girl from Arkansas, is admitted to the hospital with a chronic pneumonia that has not responded to antibiotics. Three months ago, she began to exhibit a chronic cough that eventually became productive of purulent sputum, which was occasionally streaked with blood. Two months ago, she began to exhibit "boils" on her lower extremities and back, which drained spontaneously. She was hospitalized at another hospital but failed to respond to amoxicillin and clarithromycin. C.P. denies fever, chills, or night sweats but has lost 11 pounds. Her temperature is 38.2°C. A 2 cm^2 subcutaneous, fluctuant, tender mass is seen over the right mandible and a second fluctuant mass about 4 cm wide on the lower back. In addition, several 0.5- to 1 cm^2 ulcers with heaped-up, hyperkeratotic margins are noted on the lower extremities (Fig. 78-2). Rales are heard at the right lung base. C.P.'s leukocyte count is slightly elevated at 13,500 cells/μL (SI units, WBC count, 13.5×10^9/L). A chest radiograph shows a mass-like infiltrate in the right mid-lung field (Fig. 78-3). A wet preparation of ulcer scrapings and material aspirated from a subcutaneous abscess reveal numerous broad-based, budding yeast forms with refractile cell walls and multiple nuclei typical of B. dermatitidis.

Cultures of sputum, skin scrapings, and abscess material eventually confirmed the diagnosis. What was the likely portal of entry for C.P.'s disseminated blastomycosis? Why should it be treated?

Typical of the other endemic mycoses, the primary portal of entry for B. dermatitidis is the lungs. A pulmonary origin for C.P.'s infection is supported by her history of cough with purulent, blood-streaked sputum, followed a month later with cutaneous lesions on her legs and back. An acute pulmonary infection is most often asymptomatic and, when symptomatic, usually requires only observation. Chronic pulmonary or extrapulmonary blastomycosis will develop in an unknown number of these patients. C.P.'s rales at the base of her right lung and persistent pneumonia unresponsive to antibacterials suggest a chronic pulmonary infection and a need for treatment. Chronic pulmonary disease often presents with radiographic studies often mistaken for tuberculosis or cancer; the mass-like infiltrate in her right lung on chest radiograph also is consistent with chronic pulmonary disease. Extrapulmonary infections can involve the skin (verrucous or ulcerative lesions), bone, genitourinary system (prostatitis and epididymo-orchitis), or CNS (meningitis or brain abscess). If untreated, these chronic pulmonary or extrapulmonary infections are fatal in at least

21% of patients.[129] Because C.P. presents with pulmonary and cutaneous evidence of blastomycosis, she should be treated.

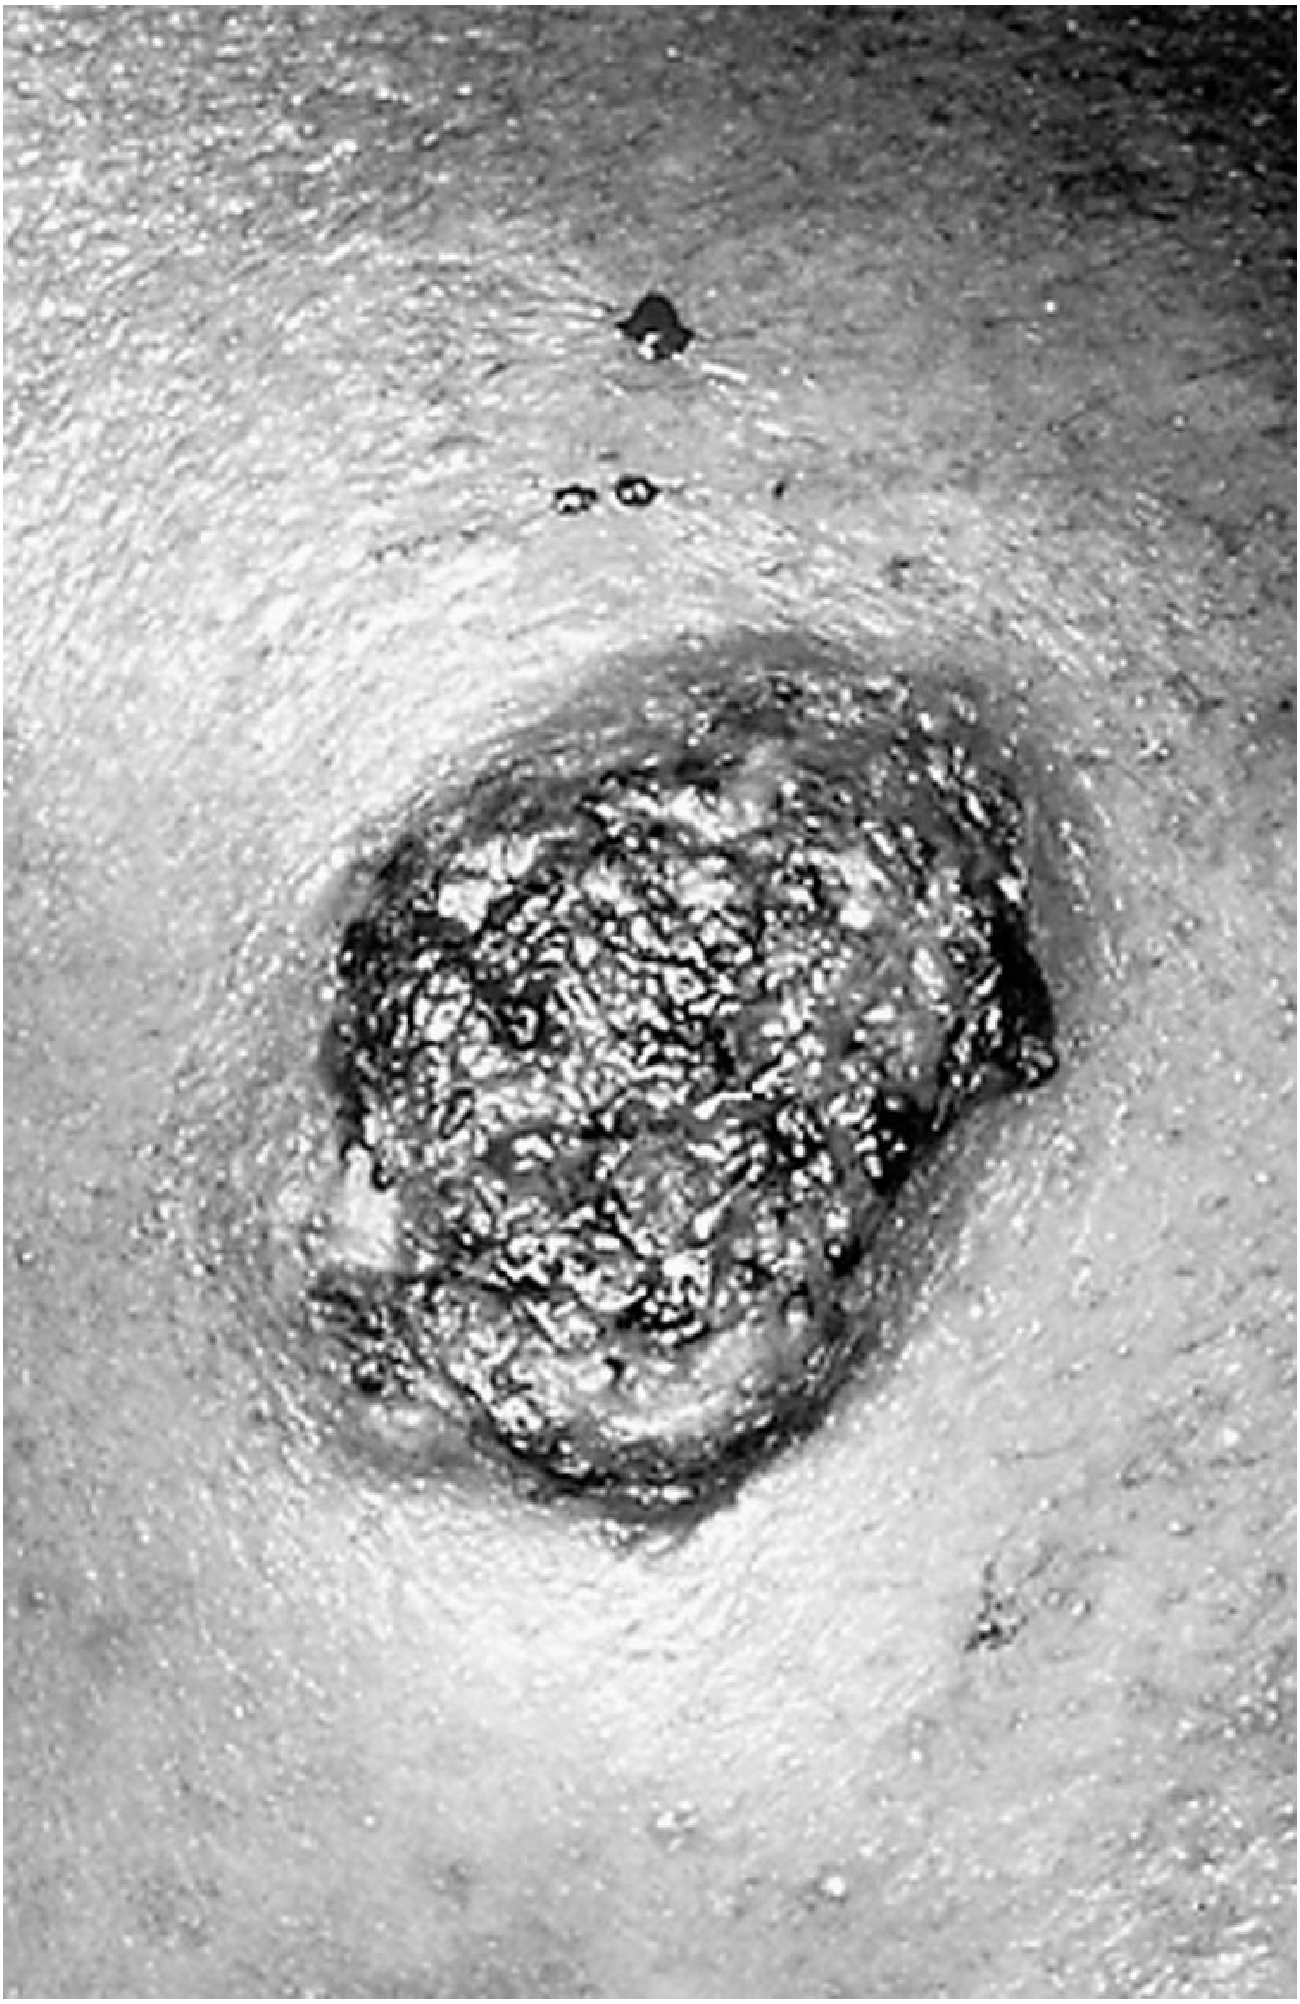

Figure 78-2 Disseminated Blastomyces dermatitidis skin ulcers.

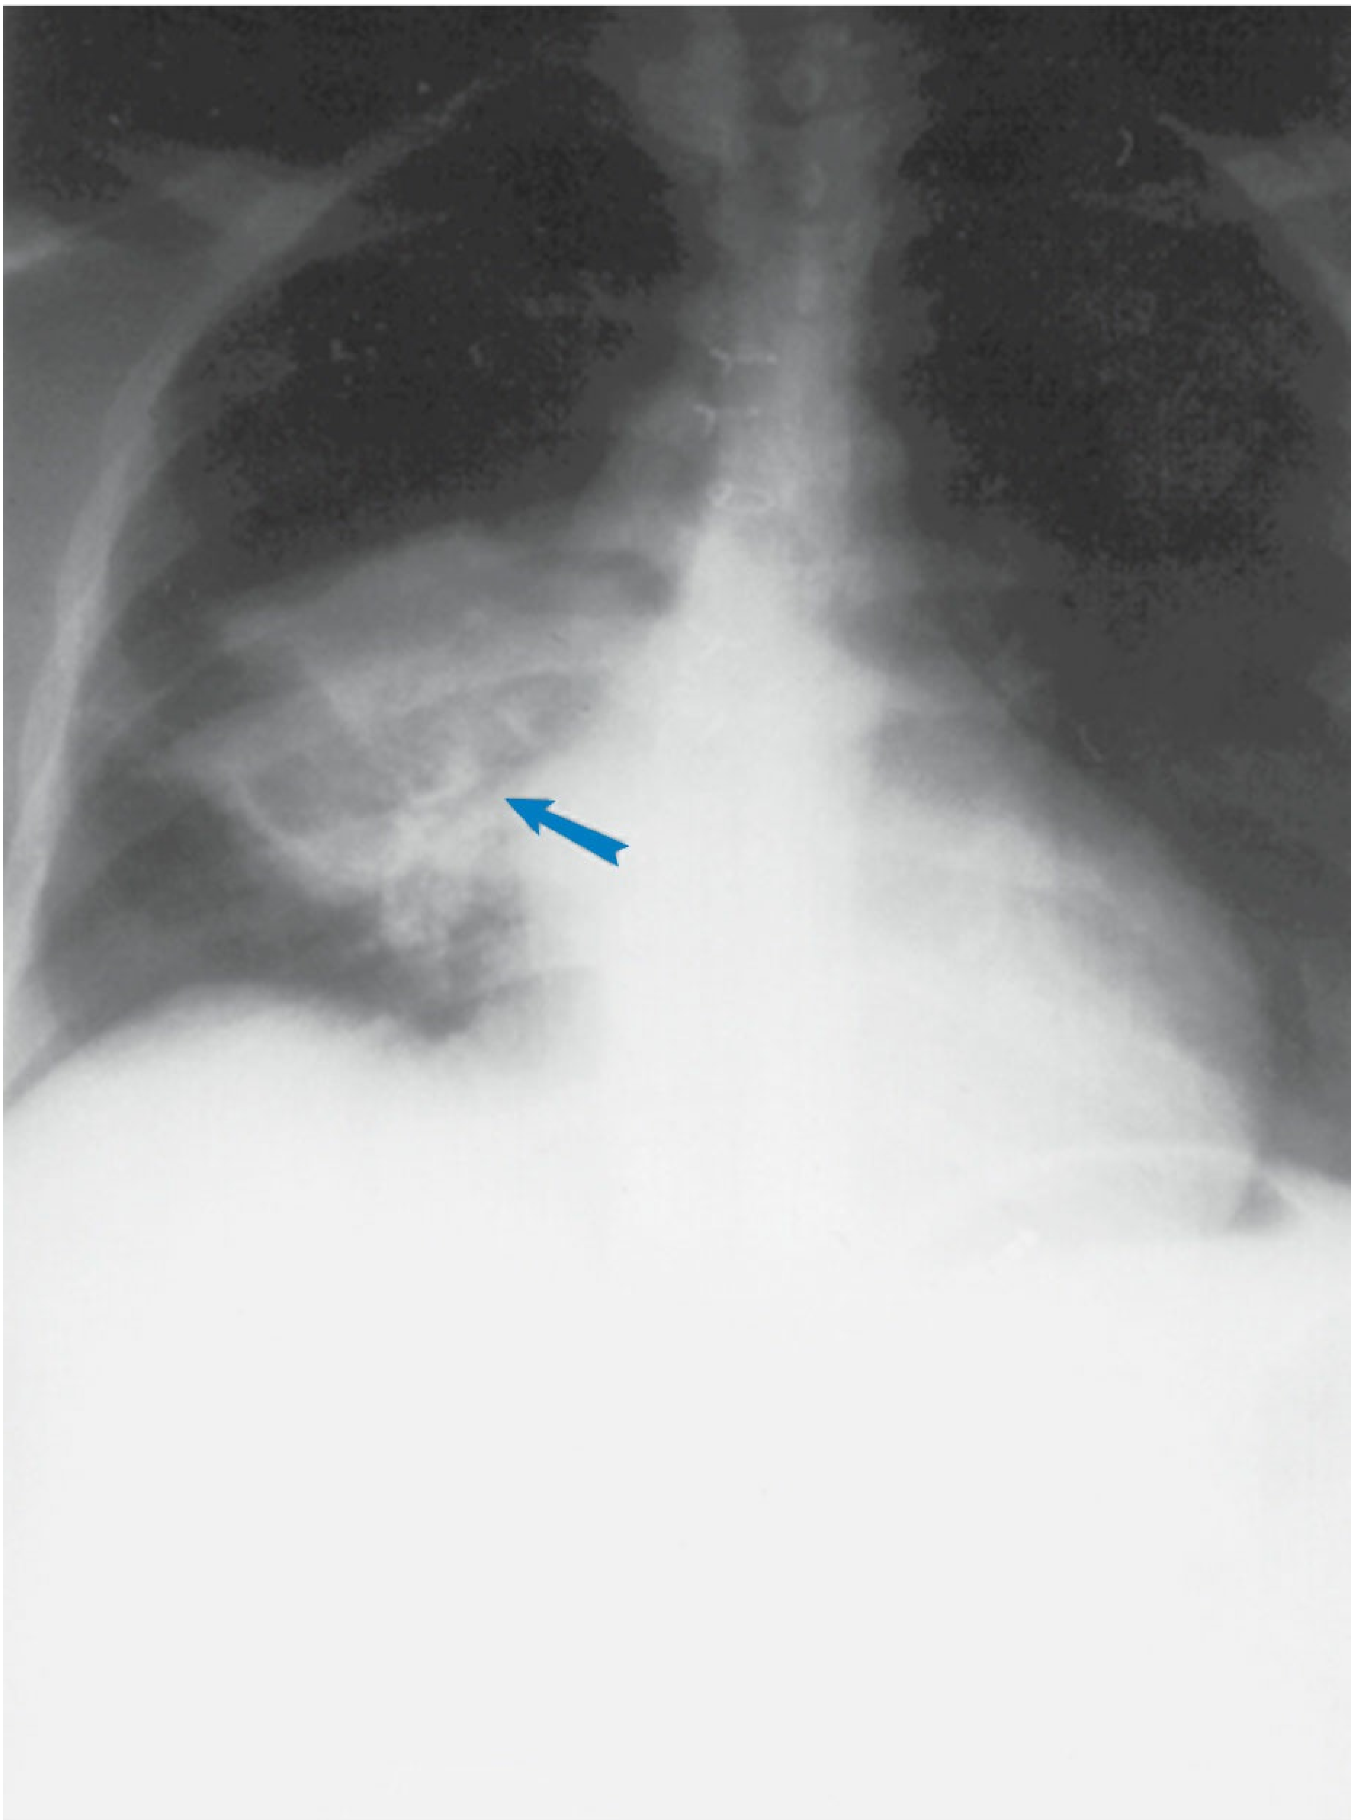

Figure 78-3 Chest radiograph of pulmonary Blastomyces dermatitidis. Arrow marks abnormality.

TREATMENT

CASE 78-5, QUESTION 2: What specific therapy should be initiated for C.P.?

Historically, AmB formulations were considered the treatment of choice for blastomycosis, and total doses of more than 2 g were associated with 97% cure rates, low relapse rates, but also, however, substantial associated toxicity.[129] Ketoconazole and itraconazole are safe, effective alternatives to AmB in patients with non–life-threatening, non-CNS infections. The NIAID–Mycoses Study Group[130] confirmed the effectiveness of azoles for the treatment of chronic pulmonary and extrapulmonary disease associated with blastomycosis and histoplasmosis. In uncontrolled evaluations of chronic pulmonary and extrapulmonary infections (excluding life-threatening or CNS), ketoconazole at dosages of 400 to 800 mg/day resulted in cure rates of about 89%, failure rates of about 6%, and relapse rates of about 5%.[130] In similar studies, itraconazole capsules 200 to 400 mg/day for a median of 6.2 months resulted in cure rates of 88% to 95%.[131] Fluconazole was ineffective at dosages less than 400 mg/day. Higher dosages (400–800 mg/day), however, are as effective as ketoconazole in non–life-threatening diseases.[132] Although these trials are neither comparative nor controlled, itraconazole is less toxic than ketoconazole and with the best benefit (efficacy) to risk (toxicity) ratio.

C.P. has mild-to-moderate disease and can be treated with an initial itraconazole dosage of 200 mg/day. If no clinical improvement is seen within 2 weeks or if the disease progresses, the dosage of itraconazole can be titrated upward in 100-mg increments to a maximal dosage of 400 mg/day. Treatment should be continued for at least 6 months. If C.P. experiences severe or meningeal disease, itraconazole should be discontinued and AmB or a lipid-based AmB product should be initiated. C.P. should be followed up for 12 months owing to the risk of relapse. Unlike histoplasmosis, skin test and serologic testing are not sufficiently sensitive to diagnose blastomycosis or evaluate the effectiveness of treatment.[130,133] Rather, patients should be evaluated closely for resolution of symptoms (constitutional and pulmonary), negative microbiologic samples, and improvement in radiographic studies.

ANTIFUNGALS IN PREGNANCY

CASE 78-5, QUESTION 3: C.P. reports she has not menstruated in 3 months, and a urine pregnancy test is positive. How does this information change the therapeutic options for her?

Data on the safety of antimycotics for treating patients who are pregnant or lactating are limited but are comprehensively reviewed according to FDA categories of the teratogenic risks of drugs (see Chapter 49, Obstetric Drug Therapy).[134,135] The systemic azoles are categorized with risk factor C. A recent Danish registration study did not find evidence of birth defects in women who took itraconazole during their first trimester.[136,137] However, the majority of women analyzed in this registry received low cumulative doses of triazoles for thrush. However, these agents should be avoided in pregnant or lactating women who are breastfeeding because of their potential teratogenicity and endocrine toxicity in the fetus or newborn. As with the azoles, griseofulvin and flucytosine have been classified with risk factor C. These agents should not be used in C.P. because the risk clearly outweighs the therapeutic benefit. Few or no data exist on the secretion of these agents in breast milk. Therefore, breastfeeding should be discouraged in women receiving these antifungal agents.

AmB and terbinafine are classified as risk factor B. Therapeutic agents in this category have no fetal risk based on animal studies, or when risk has been found in animals, controlled human studies have not confirmed the results. There are limited data regarding the use of terbinafine in pregnancy. Consequently, clinicians should avoid terbinafine use in pregnancy until published data support a B classification. Furthermore, considerable clinical experience with AmB formulations in pregnant women has documented successful treatment of systemic mycoses with no excess toxicity to either the mother or the fetus. Thus, AmB formulations have been the mainstay of antifungal therapy in pregnancy.

Histoplasmosis

TREATMENT

CASE 78-6

QUESTION 1: J.N., a 47-year-old man with severe rheumatoid arthritis, has been maintained on daily prednisone for the past 6 years; his current dosage is 20 mg/day. For the past 4 weeks, he has experienced daily fevers to 38.4°C, drenching night sweats, anorexia, and an 8.2-kg weight loss. His prednisone dosage was increased to 40 mg/day with little clinical effect. On admission to the hospital, J.N. appears chronically ill and has many of the stigmata of chronic steroid therapy. His temperature is 37.8°C with an associated rapid heart rate of 105 beats/minute. A shallow mouth ulcer is present on the hard palate. The liver is enlarged to a total span of 18 cm, and the spleen is palpable 3 cm below the left costal margin. Stool is positive for occult blood. A chest radiograph shows bilateral interstitial infiltrates (Fig. 78-4A). He is pancytopenic, with the following laboratory results:

Hematocrit, 29% (normal, 39%–45% SI units, 0.29)

WBC count, 3,500 cells/µL (normal, 4,000–11,000 cells/µL) (SI units, 3.5×10^9/L)
Platelet count, 78,000 cells/µL (normal, 130 to 400,000 cells/µL)
UA, 8 to 10 WBC/high-power field
SCr, 1.9 mg/dL (SI units, 167.96 µmol/L)
BUN, 42 mg/dL (SI units, 14.99 mmol/L urea)

The bilirubin is normal, but the aminotransferases are elevated to about 1.5 times normal, and serum lactate dehydrogenase is 10 times greater than normal. A bone marrow aspirate and biopsy of the mouth ulcer reveal multiple, small intracellular yeast forms compatible with H. capsulatum in macrophages and polymorphonuclear leukocytes (Fig. 78-4B). Cultures of blood and urine, bone marrow aspirate, and mouth ulcer biopsy grew H. capsulatum. What is the optimal antifungal therapy in this case of systemic H. capsulatum? What clinical parameters should be monitored to assess the efficacy and toxicity of J.N.'s therapy?

The treatment benefits of antifungal therapy in systemic histoplasmosis have not been well investigated. Treatment options for histoplasmosis are outlined in Table 78-7.[138] Accordingly, J.N. should be treated with an IV amphotericin product or itraconazole 2.8 mg/kg/day, and his course of therapy should be monitored for both efficacy and toxicity. The decision was made to use conventional amphotericin for J.N.

Blood and urine cultures, WBC and platelet counts (histoplasma is associated with pancytopenia), constitutional symptoms, serum lactate dehydrogenase, and hepatosplenomegaly are useful measures for evaluating the outcome of antifungal therapy of J.N.'s histoplasmosis. Anemia and chest radiographs are poor measures of treatment response. Chest radiographs often reflect calcified granulomas in chronic disease with scarring, which rarely resolve even with extensive therapy. Therefore, evaluation of deterioration on radiograph, but not of improvement, is possible. In addition, AmB-induced renal disease with secondary anemia can confuse evaluation of disease resolution. Anemia must be excluded as a prognostic indicator in patients receiving AmB for durations of 3 weeks regardless of the dose.[100]

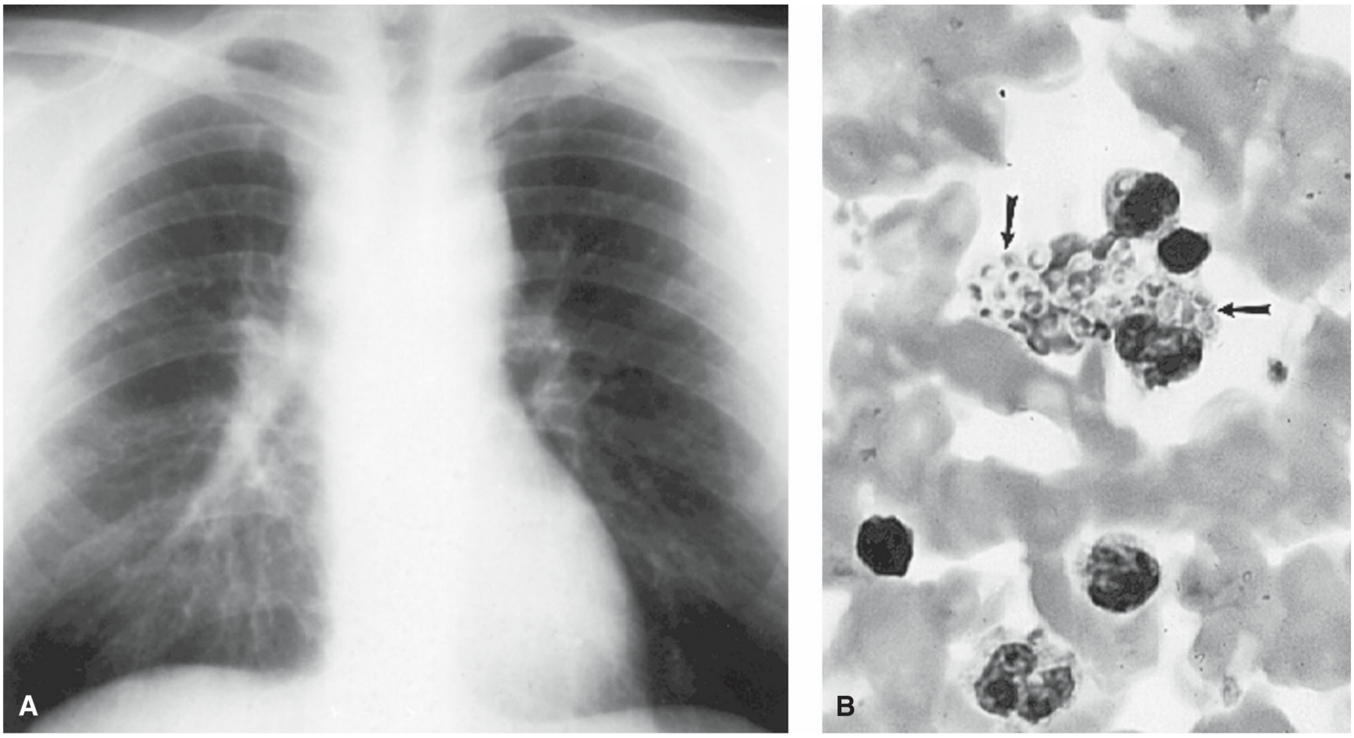

Figure 78-4 Histoplasmosis infection. **A:** Chest radiograph showing bilateral interstitial infiltrate. **B:** Gram stain of peripheral blood showing leukocytes with intracellular organisms.

Table 78-7

Treatment of Histoplasmosis

Disease	Primary	Secondary
Acute Pulmonary		
Prolonged symptomatology (>2 weeks)	Resolves spontaneously	N/A
Immunocompromised[a]	ITZ 50–100 mg/day (3–6 months)[b]	AmB 0.3–0.5 mg/kg/day[b]
Respiratory distress	AmB lipid formulation 3–5 mg/kg/day[a]	AmB 0.3–0.5 mg/kg/day
(Pao_2 <70 mm Hg)	AmB 0.5–1.0 mg/kg/day	ITZ 1.5–2.8 mg/kg/day (≥6 months)[b]
	(TD 250–500 mg) ± corticosteroids (methylprednisolone 0.5–1 mg/kg) × 1–2 weeks	ITZ (has not been investigated in life-threatening situations)
Chronic Pulmonary		
Active	ITZ (1.5–2.8 mg/kg/day 9 months)[b,c]	AmB 0.5 mg/kg/day[c]
Inactive		or KTZ 400 mg/day (≈6 mos)
Histoplasmoma	No treatment	N/A
Mediastinal fibrosis	Surgery[d]	N/A
Systemic Disease		
	AmB (TD recommended: 35 mg/kg) or lipid AmB then ITZ 2.8 mg/kg/day × up to 12 months[b]	Fluconazole 400–800 mg/day[e]

[a] Lipid formulations of amphotericin B are preferable to generic amphotericin B in HIV-infected patients.[148]

[b] Treatment should be continued until the patient is symptom-free and culture-negative for 3 months. The recommendations for duration of therapy or total doses should be used only as guides for initial therapy based upon the IDSA 2007 Guideline.[147]

[c] Indicated only for serious symptoms (i.e., hemoptysis).

[d] ITZ 200 mg daily or twice a day for 6–18 months for most patients.

[e] Fluconazole should only be used in patients who cannot take ITZ.

AmB, amphotericin B deoxycholate; ITZ, itraconazole; KTZ, ketoconazole; TD, total dose.

Diligent follow-up of patients is required because relapses occur in 5% to 15% of AmB-treated patients within 3 years. Relapses have occurred in patients who received less than 30 mg/kg total dose of generic AmB or had concomitant untreated Addison disease, immunosuppression, vascular infections (endocarditis, grafts, and aneurysms), or meningeal infections.[138] More than 90% of HIV-positive patients experience a relapse of histoplasmosis subsequent to adequate AmB therapy. A double-blind trial in immunocompromised patients (HIV) revealed that liposomal AmB was superior to AmB deoxycholate. It is not known how itraconazole is compared with liposomal AmB in those coinfected with HIV. If this patient was coinfected with HIV, a lipid-based amphotericin is preferred.[139] Even the initiation of subsequent immunosuppressive therapy is of particular concern because of the potential for reactivation (relapse) and dissemination of histoplasmosis from dormant foci, especially in patients with residual granulomas. The residual disease has been hypothesized to lead to chronic inflammatory responses and secondary strokes.[140]

Potential adverse effects to AmB should also be monitored in J.N. (e.g., infusion-related reactions, nephrotoxicity, anemia, hypokalemia, neurotoxicity, and thrombophlebitis). In addition, J.N.'s adrenal status should be monitored closely because of his long-term corticosteroid therapy and his histoplasmosis. Patients who are addisonian secondary to histoplasmosis infections appear to experience more episodes of AmB-induced acute hypotension.

AZOLE ADVERSE EFFECTS

CASE 78-6, QUESTION 2: After treatment with a total AmB dose of 750 mg, clinical improvement in J.N.'s histoplasmosis is subjectively and objectively documented. The clinician selected ketoconazole 400 mg/day as an oral substitute for his AmB regimen because of the patient's economic circumstances. Six weeks later, J.N. complains of impotence and wonders whether this could be caused by his medication. What is the likelihood that ketoconazole is the cause of J.N.'s impotence?

Ketoconazole has been associated with more adverse reactions and greater potential for drug interactions compared with itraconazole and fluconazole. The most common side effects of ketoconazole, however, are nausea and vomiting. GI distress is dose-related, with fewer GI effects with 400 mg/day compared with 800 mg/day.[138] Endocrine and hepatic toxicities are the most significant adverse effects of ketoconazole. Dose-splitting from daily to twice daily may decrease nausea and vomiting. Dose-related endocrinologic toxicities (hypoadrenalism, oligospermia, and diminished libido) have been observed during ketoconazole therapy secondary to the inhibition of mammalian sterol synthesis[13,141] and usually have been resolved with drug discontinuation. Therefore, J.N.'s complaints of impotence might well be attributed to his ketoconazole. Liver enzymes should also be monitored because an approximate 10% risk exists of elevation in transaminases and an occasional case of serious hepatitis and hepatic failure.[13,141]

The triazoles—itraconazole, fluconazole, and voriconazole—are much better tolerated and require less monitoring than ketoconazole therapy. This result has been attributed to the greater affinity of the triazoles for fungal cytochrome enzymes and less interference with mammalian enzymes.[142] Itraconazole, fluconazole (6 mg/kg/day), and voriconazole do not exhibit antiandrogenic effects, and nausea and vomiting are less common when compared with imidazoles. Abnormal elevations in liver function have been reported in 2.7% of patients receiving voriconazole during clinical trials. Abnormalities in liver function tests may be associated with higher azole dosages or serum concentrations but generally resolve either with continued therapy or dosage modification, including drug discontinuance. Liver function should be determined before and periodically throughout azole therapy because cases of serious hepatic reactions have been reported.[142] A unique adverse event associated with voriconazole is enhanced perception to light, which may be associated with higher plasma concentrations or doses. Generally, drug discontinuance is not required, although monitoring of visual acuity, visual field, and color perception is advised if therapy lasts longer than 28 days. Diarrhea, asthenia, flatulence, and eye pain have been reported with posaconazole therapy.[53] Based on these data, J.N. should be given a trial of itraconazole.

AZOLE–DRUG INTERACTIONS

CASE 78-6, QUESTION 3: J.N. chose to continue his ketoconazole therapy. He now returns with Cushingoid signs and symptoms. What potential drug or disease state interaction could be implicated as a cause of this serious problem in J.N.?

Drug interactions with systemic azoles and polyenes vary from mild inconveniences to life-threatening events. Historically, the interaction between azoles and nonsedating H_1-selective antihistamines has been serious, leading to QT prolongation and ventricular arrhythmias.[143] Although it is possible that concomitant use of corticosteroids could reduce antifungal efficacy, no clinical trial has addressed this important question. Corticosteroid serum concentrations can double with concomitant use of ketoconazole, leading to recommendations to decrease the steroid dose by 50% when ketoconazole is used. The interaction has been suggested between glucocorticoids and other azoles.[144] In addition, dexamethasone has been demonstrated to increase the clearance of caspofungin.

Other significant drug interactions with the azole antifungals involve their ability to inhibit the CYP450 enzyme system. All azoles inhibit CYP3A4, but with varying potency: Ketoconazole is the most potent inhibitor, followed by itraconazole and voriconazole, then posaconazole and fluconazole. Data on relative inhibition potency for isavuconazole are still pending. In addition to therapeutic interactions, numerous other agents are substrates to cytochrome CYP3A4 but have yet to be evaluated. Because azole antifungals could increase serum concentrations with associated potential toxicity, caution should be exercised during concomitant use. Adding complexity to voriconazole's interactions includes its propensity to inhibit CYP2C9 and CYP2C19, two isoenzymes exhibiting polymorphism, thus increasing concentrations of CYP2C9 or CYP2C19 substrates. Conversely, agents that either induce or inhibit the CYP450 system may decrease or increase, respectively, antifungal drug concentrations. Posaconazole is a substrate for p-glycoprotein efflux and is metabolized via uridine diphosphate glucuronidation; therefore, inhibitors or inducers of these clearance pathways may affect posaconazole concentrations.[51–53]

Although hundreds of drug interactions have been documented with antifungals (particularly azoles), the number of theoretical interactions probably exceeds 2000.[145] Therefore, patient medication profiles should be carefully screened before initiating and stopping antifungal therapy to assess the risk for serious drug interactions. Preferably, this screening should be performed with a frequently updated computerized interaction database, which are available commercially (Lexicomp) or free of cost (www.fungalpharmacology.org), including software for use on smartphones.

Coccidioidomycosis

SEROLOGIC TESTS

CASE 78-7

QUESTION 1: F.W., a 32-year-old Filipina woman and a lifelong resident of the Central Valley in California, is admitted to the hospital with a third recurrence of coccidioidal meningitis. Approximately 4 years ago, she was treated with a total AmB dose of 2.2 g, which resulted in a good clinical response. Nine months later, she relapsed and received a second course of AmB to a total of 1.6 g. She did well during the next 18 months and was able to return to work as a secretary. Over the past 4 months, however, F.W. has had chronic headaches, has been unable to concentrate at work, and is reported by family members to have a very labile personality. A computed tomography (CT) scan of the brain reveals mild hydrocephalus. An opening pressure of 19 mm Hg (normal, 10 mmHg) was documented at lumbar puncture. Analysis of the CSF showed:

110 WBC/μL (normal, 0 WBC/μL)
Glucose, 18 mg/dL (normal, 60% of serum glucose)
Protein, 190 mg/dL (normal, <50 mg/dL)

CF antibodies were positive in the CSF at a titer of 1:32. How should serologic tests for coccidioidomycosis be interpreted?

The most important serologic tests for fungal infections use CF, immunodiffusion, and EIA techniques. Tests for complement-fixing antibodies (i.e., CF) to the dimorphic fungi (Table 78-1) are well established, and various antigens have been used. Coccidioidin is the mycelial-phase antigen for Coccidioides immitis. Of patients with coccidioidomycosis, 61% will have coccidioidin CF titers of at least 1:32, and 41% will have titers of 1:64. Rising titers are a bad prognostic sign, and falling titers indicate clinical improvement. Therefore, F.W.'s CSF CF titer of 1:32 is consistent with active coccidioidomycosis. Immunodiffusion testing for coccidioidomycosis using coccidioidin reveals that seropositive results appear 1 to

3 weeks after the onset of primary infection in 75% of patients, and this positivity usually disappears within 4 months if the infection resolves.[146] IgG-specific and IgM-specific EIAs using a combination of antigens for C. immitis have been developed. These tests offer sensitivities of more than 92% and specificities of 98% for serum and CSF. EIA reactivity appears earlier than CF reactivity.[147,148]

ANTIFUNGAL CENTRAL NERVOUS SYSTEM PENETRATION

CASE 78-7, QUESTION 2: What is a pharmacokinetic explanation for the treatment failure of F.W.? How might this problem be overcome?

F.W. has received prolonged parenteral AmB administration, and the CSF still contains fungal organisms. Treatment failures in this case may partly be owing to the limited penetration of free AmB into the CSF.[88] Because generic AmB or lipid formulation– dissociated AmB is highly bound to lipid (90%–95%), CSF concentrations achieved are only 2% to 4% of the serum concentration[88,142]; peritoneal, synovial, and pleural fluid concentrations are less than 50% of the serum concentrations (Table 78-5). Flucytosine is not significantly bound to protein and penetrates the CSF, vitreous, and peritoneal fluids; its volume of distribution approximates that of total body water.[149] Flucytosine concentration in the CSF is 74% of the serum concentration, resulting in its extensive use in treatment of CNS mycoses, particularly cryptococcal meningitis. Flucytosine, however, has no activity in coccidioidomycosis and, therefore, cannot be used in F.W.

The volume of distribution of fluconazole approaches that of total body water,[150] and concentrations of fluconazole in CSF are approximately 60% of simultaneous serum concentrations. Ketoconazole penetrates CSF poorly, because it is highly bound to plasma proteins (>80%) and to erythrocytes (15%). Itraconazole is similar to ketoconazole in that it is greater than 99% protein-bound. Itraconazole concentrates intracellularly in host alveolar macrophages, which may account for its efficacy against some fungal CNS infections despite its inability to penetrate into the CSF.[151] Echinocandins also poorly (<5%) penetrate into the CSF. Reliable data on terbinafine, isavuconazole and posaconazole penetration are currently unavailable. Therefore, fluconazole might be an alternative to CNS instillation of AmB based upon pharmacokinetic considerations.[152,153]

Fluconazole, investigated at dosages of 400 mg/day, is useful in patients with coccidioidomycosis meningitis. Similar to amphotericin products, relapse rates are high once fluconazole therapy is stopped. Oral itraconazole 200 mg twice daily was not found to be superior to fluconazole in a controlled trial of nonmeningitis disease; however, a trend toward greater efficacy was observed, particularly in skeletal disease.[154]

INTRATHECAL AMPHOTERICIN

CASE 78-7, QUESTION 3: What adverse events might be observed with the intrathecal administration of an antifungal in F.W.?

Augmentation of systemic antifungal administration with intraventricular or intrathecal administration may improve the outcome for antifungals with poor penetration into the CSF. Intrathecal generic AmB doses in adults normally range from 0.25 to 0.5 mg diluted in 5 mL of 5% glucose.[155,156] A few studies suggest that doses larger than 0.7 mg improve the cure rate and decrease relapse. Cisternal or intraventricular administration is recommended as the routes of choice because of flow characteristics of CSF from the ventricles to the spinal cord. When lumbar administration has been necessary, agents are administered in a hypertonic solution of 10% glucose, and the patient is placed in a Trendelenburg position in an attempt to improve distribution of the drug to the basilar meninges and ventricles and reduce local toxicity. Voriconazole, caspofungin, and the lipid amphotericin formulations have been used, but not evaluated in controlled trials.

Cisternal antifungal administration has been associated with headaches, nausea, vomiting, cranial nerve paresis, and cisternal hemorrhage caused by needle trauma. An Ommaya reservoir often is used to facilitate intraventricular administration of AmB formulations. Common complications of these devices include shunt occlusion, bacterial colonization or bacterial meningitis, Parkinsonian symptoms, and seizures.[156–158] In the past, lumbar administration was used because it is simpler, but it often must be discontinued because of chemical arachnoiditis, headache, transient radiculitis, paresthesia, nerve pulses, difficulty voiding, impaired vision, vertigo, and tinnitus. Acute toxic delirium, demyelinating peripheral neuropathy, and spinal cord injury have also been reported.[159–162] Regardless of the substantial and serious adverse effects, intraventricular administration may be effective in treating patients with meningitis who have severe disease or who are pharmacologic nonresponders.

Aspergillosis

EMPIRIC THERAPY (NEUTROPENIC HOST)

CASE 78-8

QUESTION 1: M.Z., an otherwise healthy 29-year-old man, who received an allogeneic stem cell transplantation 12 days ago. He has had no serious complications associated with his chloroquine-induced aplastic anemia during his 7-month wait for transplant. On transplant Days 5 to 2, induction therapy was initiated with cyclophosphamide (50 mg/kg) and total body irradiation, and then bone marrow from his human leukocyte antigen–compatible brother was infused on Day 0. The onset of neutropenia was noted on Day 3, and the WBC count was 50 cells/μL. M.Z. has complained only of stomatitis and diarrhea before Day 5. On that morning, he was complaining of fever, chest pain, and headache. On physical examination, his

---

temperature was 37°C. Empiric antibiotics were added, but by Day 8, he was not clinically improving. A CT scan of the chest and sinuses revealed a nodular pleural–based opacity with ground-glass attenuation (halo sign) in his right lung. What therapeutic options should be considered for this patient?

Empiric antifungal therapy in a neutropenic host should be initiated when a patient is febrile for more than 96 hours on appropriate antibiotics. Routine empiric therapy for a patient without evidence of deep-seated fungal infection was historically generic AmB 0.3 to 0.6 mg/kg/day or fluconazole 200 to 400 mg/day until the absolute neutrophil count is greater than 500 cells/µL.[163] Therapy results in resolution of signs and symptoms in up to 64% of patients.

CASE 78-8, QUESTION 2: What is the role of lipid formulations of AmB?

Because mold infections are of concern in this neutropenic patient who received an allogeneic stem cell transplant, mold-active antifungal therapy should be started immediately. A large, well- controlled, double-blind AmB 0.6 mg/kg/day was compared with liposomal AmB 3.0 mg/kg/day in febrile neutropenic patients. Patients who were febrile more than 96 hours and neutropenic (<500 cells/µL) experienced equal survival and clinical success of approximately 50% for both the agents.[164] Success rates have been similar with other agents, including liposomal AmB (34%), caspofungin (34%),[165] voriconazole, or itraconazole.[166,167] It is important to remember that fever is a late and insensitive measure of infection. Prevention of breakthrough invasive fungal infection may be the most important indicator of an agent's efficacy. Using this measure comparing the various trials, voriconazole appears to be the most effective agent, voriconazole versus liposomal AmB (1.9% vs. 5%) and AmB versus liposomal AmB (3.2% vs. 7.8%), although crude mortality rates were similar in the two patient groups (8% vs. 6%, respectively).[164,167] Selection of expensive, but less toxic, agents should be weighed against the morbidity and mortality associated with invasive fungal disease.

TREATMENT OF ASPERGILLOSIS

CASE 78-8, QUESTION 3: Fiberoptic bronchoscopy performed to evaluate the nodular lesion in chest CT revealed eroded bronchioles with necrotic tissue, and methenamine silver nitrate stain of a biopsy sample revealed fragmented, closely septated hyphal bodies branched at 45° angles. The samples were sent to microbiology for cultures. A galactomannan test from the bronchial wash was positive at an index of 1.1. All previous blood and sputum cultures have been negative. The diagnosis at this time is probable aspergillosis. What treatment steps should be taken?

Drug therapy should be approached by first determining whether the infection is likely to be invasive or noninvasive disease (Fig. 78-5). Most patients inhale Aspergillus species and never become symptomatic or exhibit only mild hypersensitivity pneumonitis. Pepper can be a common food source for Aspergillus exposure. Invasive infections are more likely to occur in immunocompromised patients, especially those with prolonged neutropenia or patients who receive high dose (i.e., more than 1 mg/kg/day prednisone equivalent) or corticosteroids or other T-cell immunosuppressive therapy (i.e., alemtuzumab and anti-thymocyte globulin) to treat acute graft versus host disease following stem cell transplantation or organ rejection after solid organ transplantation. Allogeneic hematopoietic stem cell transplantation (HSCT) has a much greater infection rate and mortality compared with autologous HSCT.[168] A classic observation reported by radiology is a “halo” sign or a “crescent” sign identified on CT, which is highly suggestive of invasive aspergillosis. However, the halo sign is not specific, because other bacterial viral, malignant, or autoimmune conditions can produce similar radiographic findings. The halo sign is also transient and is less common after 1-week of infection. Typically these nodular lesions will enlarge (even with effective antifungal therapy) and then cavitate when a patient’s neutrophil count recovers, forming another distinguishing CT abnormality for invasive mold disease—the air crescent sign.[169]

A majority invasive aspergillosis cases are now diagnosed based on a compatible clinical and radiographic picture described above and the results of an ELISA antigen test for a cell wall polysaccharide in Aspergillus spp.-galactomannan. Serum galactomannan test is a fairly sensitive and specific test (80%–90%) in neutropenic patients with aspergillosis who rapidly progress to angioinvasive disease in the lung. The test is less sensitive in non-neutropenic patients who initially present with bronchial invasive patterns of pneumonia before angioinvasion or in patients receiving mold-active antifungal therapy.[170] In these populations, testing of bronchial alveolar lavage fluid for galactomannan antigen has better sensitivity than serum. False-positive test findings have been associated with Bifidobacterium sp. colonization in pediatric GI tracts, other eukaryotic infections (i.e., Trichosporon, Fusarium, Saccharomyces, Hisplasma, or Acremonium), and administration of piperacillin–tazobactam or calcium gluconate, which is of concern for clinicians using this test for screening in areas with low case rates. Galactomannan antigen is a useful prognostic indicator for therapeutic outcome in confirmed cases or as a screen in areas with high case rates. The subjective and objective data in this case clearly represent invasive symptomatic disease necessitating aggressive treatment.

Aspergillosis is a model for invasive mold infections that have a propensity to invade blood vessels and tissue. Antifungal therapy should be initiated rapidly and aggressively (Table 78-8) in conjunction with the removal or reversal of immunosuppression if possible. Definite or probable invasive aspergillosis should be treated with voriconazole, isavuconazole, or lipid amphotericin B formulation (i.e., liposomal AmB 3–5 mg/kg/day), or combination therapy.[171–173] In a recent European organization for research and treatment of cancer (EORTC)/Mycoses study group (MSG) trial performed in patients with probable or proven aspergillosis, a combination therapy with voriconazole plus anidulafungin for at least 2 weeks was associated with an 8% reduction in 6-week all-cause mortality versus voriconazole monotherapy alone, although this difference was not statistically different in the context of the design of the clinical trial.[174] Therefore, the optimal approach for using combination therapy in invasive aspergillosis remains unresolved. Despite early and intensive therapy, mortality from invasive aspergillosis can be greater than 50%.[175] In unresponsive patients, a lipid AmB formulation in combination therapy or possibly triazole should be considered.[171–177] Importantly, some less common molds intrinsically resistant to several antifungal classes (i.e., Mucorales, Fusarium spp. Scedosporium spp.) occasionally present as infections or breakthrough infections that may be indistinguishable from invasive aspergillosis.

Patients with mild-to-moderate Aspergillus should be treated with voriconazole or isavuconazole.[166] Clinical and microbiologic cure rates of 50% to 71% have been reported for voriconazole- or isavuconazole-treated invasive aspergillosis. In a comparative trial of voriconazole versus isavuconazole for patients with proven or probable aspergillosis, patients randomized to receive isavuconazole had similar clinical response and mortality rates as voriconazole-treated patients with lower rates of ocular, hepatic, and cutaneous adverse reactions.[178,179]

Table 78-8

Therapeutic Options for Treatment of Aspergillosis

Disease	Primary	Secondary
Hyalohyphomycetes		
Aspergillosis		
Allergic bronchopulmonary	Prednisone 1 mg/kg/day followed by 0.5 mg/kg/day or every other day × 3–6 months; no antifungal therapy	ITZ 200 mg BID × 4 months[a]
Aspergilloma	Observation	Surgery[b]
Systemic (invasive)	Isavuconazole 300 mg IV 3 times daily for 48 hours LD, then 300 mg daily	Amphotericin B lipid formulation[c], or Posaconazole 300 mg twice daily LD, then 300 mg daily

		or/and Combination therapy with an echinocandin[d]

[a] Treatment should be continued until the patient is symptom-free and culture-negative for 3 months. Noted durations or total doses should be used only as a compass to help guide therapy.

[b] Indicated only for serious symptoms (e.g., hemoptysis).

[c] Lipid formulations of amphotericin B should be utilized preferentially in these patients.

[d] anidulafungin (AFG) 200 mg parenterally; caspofungin (CFG) 70 (50) mg parenterally on Day 1 (2–14); micafungin (MFG) 70 mg parenterally; flucytosine (5FC) 150 mg/day parenterally.

AmB, amphotericin B; BID, twice daily; ITZ, itraconazole; LD, loading dose; TID, three times daily.

Cryptococcosis

CASE 78-9

QUESTION 1: D.W., a 48-year-old man, was hospitalized with fever and severe headache. His history was significant for Hodgkin lymphoma, which is in remission. Lumbar puncture revealed the following:

Opening pressure of 280 mm Hg (normal, 10 mm Hg)
WBC count, 50 leukocytes/μL (normal, 0 leukocytes/μL)
Positive India ink preparation
Cryptococcal antigen titer, 1:4,096

Serology for HIV infection was negative. Culture of the CSF eventually grew C. neoformans. The presumptive diagnosis is cryptococcal meningitis. What are the treatment options for D.W.?

Currently, only two therapeutic options exist for meningeal cryptococcal disease: an AmB formulation with or without flucytosine and fluconazole. Flucytosine cannot be used alone for therapy or prophylaxis because of the rapid development of resistance. This yeast is also resistant to echinocandins. Patients, whether infected with HIV or not, have improved treatment outcomes when the combination of AmB and flucytosine is used.[180,181] Furthermore, when flucytosine (100–150 mg/kg/day divided into four daily doses) is used in combination therapy, the dose of AmB may be reduced to 0.3 to 0.6 mg/kg/day, which decreases the frequency of dose-related AmB toxicity. In patients who cannot be treated with flucytosine, the dosage of AmB must be increased to more than 0.6 mg/kg/day. AmB 1 mg/kg/day is more rapidly fungicidal than 0.7 mg/kg/day when used with 5FC. Liposomal AmB 3 mg/kg/day can and probably should be used instead of the nonlipid formulations in this disease owing to presumed increase in safety.[182]

Fluconazole is an alternative to AmB in patients infected with HIV with cryptococcal meningitis. It is important to be mindful of the following caveats, however: Sterilization of the CSF occurs more rapidly, and mortality is lower during the first 2 weeks of therapy in patients treated with AmB as compared with fluconazole.[182] Early mortality was especially high in fluconazole-treated patients who presented with altered mental status.[183–185] Thus, initial therapy of cryptococcal meningitis in patients with mental status changes should be initiated with AmB for at least 2 weeks or until the patient has stabilized clinically.

A landmark study on patients with cryptococcal meningitis compared patients randomized to receive either amphotericin B 1 mg/kg/day for 4 weeks or a 2 week induction regimen of amphotericin B 1 mg/kg/day plus flucytosine (1 mg/kg/day) or fluconazole (400 mg twice daily).[185] At Day 70 after randomization, significantly fewer deaths were observed in patients receiving amphotericin B plus flucytosine versus patients receiving amphotericin B alone (hazard ratio: 0.61, 95% CI: 0.39–0.97, P = 0.04). Combination therapy with fluconazole did not significantly impact survival over amphotericin B monotherapy. Notably, the amphotericin B-flucytosine combination was associated with more rapid clearance of yeast from the CSF versus other regimens. Rates of adverse effects were similar in all groups even though neutropenia was slightly more common in patients receiving amphotericin B-flucytosine or amphotericin B-fluconazole combinations versus amphotericin B monotherapy (34% and 32% vs. 19%, P = 0.04).

Fluconazole 400 mg/day may be an acceptable option in patients with less severe disease in all other patients. Another alternative may include liposomal AmB 4 to 6 mg/kg/day for 21 days. Until larger clinical studies have been completed, however, this regimen cannot be recommended over generic AmB (see Chapter 77, Opportunistic Infections in HIV-Infected Patients).[181]

In D.W., initial treatment should focus on elimination of all factors leading to immunosuppression. Antifungal therapy should be initiated immediately with AmB 0.3 to 0.6 mg/kg/day plus flucytosine 100 to 150 mg/kg/for a minimum of 6 weeks to optimize the chance of a cure, especially in transplant recipients.[185] In addition, CSF hypertension, usually presenting as headache, should be resolved through therapeutic spinal tap. Acetazolamide should be avoided in these cases.[186] An unfortunate consequence of eliminating immune suppression is immune reconstitution syndrome (IRIS). This syndrome is most commonly observed in HIV-infected patients started on antiretrovirals who experience complications secondary to new onset inflammatory reactions from replenished leukocytes. IRIS may make it appear these patients are failing antifungal therapy.

CASE 78-9, QUESTION 2: What parameters should be monitored while D.W. is treated with flucytosine?

The most common side effect of flucytosine is GI distress (e.g., nausea, vomiting, and diarrhea). Although flucytosine is not metabolized per se by mammalian cells, gut flora may be responsible for metabolism of flucytosine to fluorouracil. This toxic metabolite has been speculated to account, in part, for the GI distress and bone marrow toxicity associated with flucytosine therapy.[187] Other flucytosine adverse effects include leukopenia, thrombocytopenia, and hepatotoxicity. Dose-dependent bone marrow suppression, which can be fatal, generally is seen in patients whose serum concentration of flucytosine is greater than 100 mcg/mL. Thus, it is important to monitor blood concentrations and maintain concentrations below this level.[181,183] If assays for flucytosine serum concentrations are unavailable, signs and symptoms of bone marrow suppression or worsening renal function should result in a dosage reduction or discontinuation of the drug. Flucytosine is eliminated by glomerular filtration, with 80% to 95% of the dose excreted unchanged in the urine. Renal excretion of flucytosine is directly related to creatinine clearance, and dosages should be adjusted based on creatinine clearance to prevent the accumulation to toxic concentrations in patients with renal impairment.[101] Patients with creatinine clearances of 10 to 40 mL/minute should have the dosage of flucytosine reduced by 50% (usual dose, 37.5 mg/kg every 12 hours). For patients with creatinine clearance less than 10 mL/minute, dosing should be initiated at 37.5 mg/kg/day, with frequent monitoring of flucytosine serum concentrations. Dosage adjustment and close monitoring also are required for patients receiving hemodialysis, and it is recommended that the dose be given postdialysis.

CASE 78-9, QUESTION 3: When is combination antifungal therapy indicated?

In vitro results of antifungal combinations against many common mycotic pathogens have been variable. These incomplete and inconsistent findings have been attributed to variable incubation times, variable concentrations of antifungal agents, and the sequence of antifungal addition. As a result, clinical decisions about combination therapy should be based on patient-specific in vivo evaluations. Because of the limited clinical data, combination antifungal therapy should be initiated cautiously. Except for the treatment of cryptococcal meningitis and disseminated aspergillosis, combination therapy should be reserved for cases of treatment failure (disseminated candidiasis) with no other established pharmacologic options for therapy or mold infections with high mortality rates.

Viral Infections

Milap C. Nahata, Neeta Bahal O'Mara, and Sandra Benavides

	CORE PRINCIPLES	CHAPTER CASES
1	Herpes simplex virus (HSV) encephalitis is associated with significant morbidity and mortality. Intravenous acyclovir for a 21-day period is the therapy of choice.	**Case 79-1 (Questions 2, 4)**
2	Neonatal herpes can present with mucocutaneous, ocular infection, as well as encephalitis and disseminated HSV infection. Transmission can be acquired during the first trimester of pregnancy or during vaginal delivery in an infected mother.	**Case 79-2 (Questions 1, 2)**
3	Herpes labialis is the most common oral-facial HSV infection and is usually self-limiting in an immunocompetent host. Patients who are immunocompromised must be treated with antiviral therapy, primarily oral or intravenous acyclovir or oral valacyclovir.	**Case 79-3 (Question 1),** **Case 79-4 (Question 1)**
4	Individuals with progressive varicella, those with extracutaneous complications, or those at high risk for developing complications to varicella infection benefit from antiviral therapy.	**Case 79-7 (Question 1),** **Case 79-8 (Question 1)**
5	The goal of pharmacotherapy of herpes zoster is to reduce pain and duration of rash and to prevent the development of postherpetic neuralgia (PHN). These outcomes can be accomplished with the use of oral acyclovir, famciclovir, or valacyclovir. For the treatment of PHN, topical capsaicin gels, creams and patches, topical lidocaine patches, and oral gabapentin and pregabalin are efficacious.	**Case 79-9 (Question 1)**
6	Neuraminidase inhibitors, such as zanamivir, oseltamivir, and peramivir, are indicated for the treatment of influenza if used within 48 hours after the onset of symptoms. Zanamivir is administered by oral inhalation with bronchospasm the most common adverse drug reaction. Oseltamivir is administered orally, with nausea, vomiting, and headache as common side effects. Peramivir is administered intravenously and has been associated with hypersensitivity reactions, such as Steven–Johnson syndrome.	**Case 79-11 (Question 2)**
7	Influenza vaccination is the most effective mechanism to prevent the flu. However, certain high-risk populations may require additional prophylaxis with oseltamivir or zanamivir.	**Case 79-10 (Question 2)**
8	Infants at high risk for severe disease caused by respiratory syncytial	**Case 79-13 (Questions 1, 2)**

	virus (RSV) should receive monthly intramuscular injections of palivizumab for a total of five doses during RSV season.	
⑨	West Nile virus can cause disease ranging from a febrile infection to encephalitis. Treatment is supportive; however, ribavirin and interferon-α-2b have been tried in this patient population. Clinical trials evaluating the use of immunoglobulin, monoclonal antibodies, and vaccines are ongoing.	**Case 79-14 (Questions 1, 2)**
⑩	The common cold is the most prevalent viral infection. Numerous pathogens can cause this respiratory infection, including rhinovirus, coronavirus, parainfluenza, RSV, adenovirus, and enterovirus. There are currently no products that have been conclusively shown to prevent or treat the common cold.	**Case 79-15 (Question 1)**

Viral infections are common causes of human disease. An estimated 60% of illnesses in developed countries result from viruses, compared with only 15% from bacteria. These include the common cold, chickenpox, measles, mumps, influenza, bronchitis, gastroenteritis, hepatitis, poliomyelitis, rabies, and numerous diseases caused by the herpesvirus. Upper respiratory tract infections, such as the common cold or influenza, are among the most common reasons for visits to a health care professional.[1] Most of these patients have a self-limiting illness; however, certain viral infections, such as influenza, can cause significant mortality, particularly in the elderly. During the worldwide Spanish influenza epidemic of 1918 to 1920, 20 to 100 million people died.[2] Although influenza vaccines reduce the morbidity and mortality associated with this disease, for many other potentially severe viral infections, including herpes encephalitis and neonatal herpes, no vaccine is available.

Substantial progress has been made in antiviral chemotherapy as a result of advances in molecular virology and genetic engineering. Antiviral agents can be designed to inhibit functions specific to viruses, which maximizes their therapeutic benefits and minimizes adverse effects.

Current technology also permits rapid diagnosis of viral diseases. It is now possible to make a specific diagnosis of several viral illnesses within hours to a few days; previously, a specific diagnosis often took days to months. These improved diagnostics have facilitated rapid selection of an appropriate antiviral drug.

This chapter describes the etiology, pathogenesis, and treatment of common viral infections. Specific case presentations illustrate the optimal use of antiviral drugs in patients with viral infections.

HERPES SIMPLEX VIRUS INFECTIONS

Herpes viruses are responsible for a broad spectrum of diseases including acute life-threatening illness (herpes encephalitis and neonatal herpes), as well as more chronic, recurrent infection (genital herpes). Antivirals significantly decrease the morbidity and mortality in most of these infections.[3]

Herpes Encephalitis

Herpes simplex virus (HSV) encephalitis is the most common sporadic viral infection of the central nervous system (CNS). HSV encephalitis occurs in up to 500,000 people yearly, although this may be an underestimate owing to difficulties in diagnosis. It typically occurs in two populations, those 6 months to 20 years of age and those older than 50 years. It is characterized by the acute onset of fever, headache, decreased consciousness, and seizures. Any child with fever and altered behavior should be evaluated for HSV encephalitis. Without treatment, mortality approaches 70% and some morbidity is evident in 97% of survivors. Only 2.5% of patients recover sufficiently to lead normal lives.[3]

Herpes simplex virus type 1 (HSV-1) is the etiologic agent in most patients with herpes encephalitis, but herpes simplex virus type 2 (HSV-2) is more common in newborns. The infection may be localized to the brain or involve cutaneous and mucous membranes. Although any area of the brain can be involved, the orbital region of the frontal lobes and the temporal lobes are most often affected.[4]

Herpes encephalitis is often difficult to diagnose. A computed tomography (CT) scan is usually indicated to rule out other conditions, such as brain abscess or other space-occupying lesions. The CT or radionuclide scans may be unremarkable early in the course of the disease.

Cerebrospinal fluid (CSF) examination usually reveals pleocytosis (predominately lymphocytes) with 50 to 2,000 white blood cells (WBCs)/mcL. Polymorphonuclear leukocytosis and red blood cells (RBCs) may also be seen. Many patients have an elevated protein level in the CSF (median, 80 mg/dL; normal values differ per age, e.g., if ≥6 months, 15–45 mg/dL).

The electroencephalogram (EEG) is the most sensitive but least specific test. There are usually CT or brain scan abnormalities, but these may take a day or two longer to appear. The EEG, CT, and brain scan findings compatible with HSV encephalitis can be mimicked by other conditions, and a brain biopsy is required to clearly establish the diagnosis. Rapid diagnosis of herpes encephalitis by a polymerase chain reaction (PCR) assay of HSV DNA in the CSF is available at most medical centers. This is a highly sensitive, specific, and rapid method for diagnosing herpes encephalitis.[5]

CLINICAL PRESENTATION

CASE 79-1

QUESTION 1: R.F., a 7-year-old boy weighing 20 kg, was seen in the emergency department (ED) after a seizure. For the previous 3 days, R.F. had decreased appetite, headache, and fever (101°F–102°F), and was lethargic and disoriented. His leukocyte count was 13,000/mcL with a shift to the left. Ceftriaxone (50 mg/kg intravenously [IV] every 12 hours) and dexamethasone (0.15 mg/kg IV every 6 hours) were initiated for presumed bacterial meningitis. Phenobarbital (5 mg/kg IV every 24 hours) was given for seizure control. The CSF was normal, and no bacteria could be cultured. Acyclovir 20 mg/kg IV every 8 hours was started immediately. A PCR analysis of HSV-1 was positive. What findings in R.F. are consistent with the diagnosis of herpes encephalitis?

Fever, headache, lethargy, and disorientation are common features of herpes encephalitis. As illustrated by R.F., the CSF examination can be normal in some patients. A negative CSF culture suggests the absence of a bacterial infection.[6] However, the positive HSV-1 DNA by PCR analysis confirms the diagnosis of herpes encephalitis.

TREATMENT: ACYCLOVIR

CASE 79-1, QUESTION 2: What is the treatment of choice for R.F.'s herpes encephalitis?

Two studies comparing acyclovir and vidarabine (no longer marketed in the United States) have demonstrated that IV acyclovir (10 mg/kg every 8 hours for 10 days) is the treatment of choice in patients with herpes encephalitis.[7,8] The 12-month all-cause mortality was 25% in the acyclovir-treated group and 59% in the vidarabine-treated group. Notably, nearly one-third of the acyclovir-treated patients returned to normal life, compared with only 12% of those treated with vidarabine.[9]

Acyclovir is the treatment of choice for R.F. because it has been shown to decrease morbidity in patients with herpes encephalitis. Acyclovir should be started as soon as HSV encephalitis is suspected because early initiation of therapy is associated with improved outcome. Therapy should be continued for at least 21 days.[10] The role of corticosteroids in the treatment of herpes encephalitis is not well defined. One small, nonrandomized trial found that corticosteroid therapy, in combination with IV acyclovir, was associated with an improved outcome.[11] However, prospective, randomized trials are needed before routine use of corticosteroids can be recommended.[12] Acyclovir-resistant herpes

---

is not an important consideration in the management of herpes encephalitis in most patients.

Adverse Effects

CASE 79-1, QUESTION 3: What adverse effects can occur with IV acyclovir therapy in R.F.? How should these be monitored, and how can they be minimized?

Acyclovir is a relatively safe drug, but renal toxicity associated with IV acyclovir is well described (Table 79-1). Blood urea nitrogen (BUN) and serum creatinine (SCr) levels can increase in 5% to 10% of patients; however, these changes are generally reversible. Acyclovir is relatively insoluble: maximal urine solubility at 37°C is 1.3 mg/mL. Consequently, the mechanism of acyclovir-associated renal disease is a transient crystal nephropathy, which may occur at high acyclovir concentrations.[9]

Other common adverse effects include gastrointestinal (GI) complaints, such as nausea and vomiting and, less commonly, neurologic disturbances, including lethargy, tremors, confusion, hallucinations, and seizures.[9,25] Neurotoxicity appears to be more common in patients with impaired renal function and is reversible. Finally, IV acyclovir can cause phlebitis and pain at the injection site.[9] This complication can be minimized by administering acyclovir at a concentration of 5 mg/mL (maximum, 7 mg/mL).[25]

Renal function tests, including BUN, SCr, and urine output, should be monitored in R.F. To minimize the risk of acyclovir nephrotoxicity, R.F. should be well hydrated, and each acyclovir dose should be infused for 1 hour. In addition, the IV infusion site should be inspected for inflammation and pain, and R.F. should be asked about pain at the infusion site.

Conversion to Oral Therapy

CASE 79-1, QUESTION 4: After 7 days of IV acyclovir, R.F. is alert, responsive, actively moving about, and eating a normal diet. The intern suggests switching him to oral acyclovir and discontinuing IV therapy. Is this appropriate?

Oral acyclovir therapy is inappropriate for R.F. On the basis of studies in adults, the absorption of acyclovir after oral administration is variable, slow, and incomplete. The relative bioavailability (F) of acyclovir is low (F = 0.15–0.30) and decreases with increasing doses.[26] The mean peak plasma concentration has ranged from only 0.83 to 1.61 mcg/mL after multiple acyclovir doses of 200 to 800 mg.[26] Thus, with only approximately 50% of acyclovir penetrating the blood–brain barrier, the concentrations of acyclovir in the CSF may be inadequate for R.F. There is only very limited information regarding the use of oral valacyclovir for therapy. A small pharmacokinetic trial of oral valacyclovir in patients with HSV encephalitis found that while therapeutic CSF concentrations of valacyclovir were achieved, CSF concentrations dropped over time, likely because of resolution of inflammation of the blood–brain barrier. Consequently, switching to oral therapy cannot be recommended at this time and therapy with IV acyclovir should be continued to complete a 21-day course (Table 79-2).[27]

Table 79-1

Adverse Effects of US Food and Drug Administration (FDA)–Indicated Drugs for Various Viral Infections

Drug	Adverse Effects
Acyclovir[9]	Local irritation, phlebitis; increased SCr, BUN; nausea, vomiting; itching, rash; increased liver transaminases; CNS toxicity; hematologic abnormalities
Amantadine[13]	Nausea, dizziness (lightheadedness), insomnia (5%–10%); depression, anxiety, irritability, hallucination, confusion, dry mouth; constipation, ataxia, headache, peripheral edema, orthostatic hypotension (1%–5%); suicide ideation or attempt (<1%)
Cidofovir[14]	Nephrotoxicity; neutropenia; rash; headache; alopecia; anemia; abdominal pain; fever; infection; ocular hypotonia; nausea, vomiting; asthenia; diarrhea
Famciclovir[15]	Headache; nausea; diarrhea
Foscarnet[16]	Fever, nausea, vomiting; renal dysfunction; anemia; diarrhea; headache; electrolyte abnormalities; bone marrow suppression; seizure; anorexia; abdominal pain; mental status changes; paresthesia, peripheral neuropathy; cough, dyspnea; rash; first-degree AV block, ECG changes
Ganciclovir[17]	Increased SCr; anemia; neutropenia, pancytopenia, thrombocytopenia; abdominal pain, anorexia; diarrhea; nausea, vomiting; retinal detachment, vitreous hemorrhage, cataracts, corneal opacification; neuropathy; rash
Oseltamivir[18]	Nausea, vomiting; diarrhea; abdominal pain; dizziness, vertigo, insomnia; self-injury and psychosis
Ribavirin[19]	Worsening of respiratory status, bacterial pneumonia, pneumothorax, apnea, ventilator dependence; cardiac arrest, hypotension; rash; conjunctivitis
Rimantadine[20]	CNS (insomnia, dizziness, headache, nervousness, fatigue); GI (nausea, vomiting, anorexia, dry mouth, abdominal pain) (1%–3%)
Trifluridine[21]	Burning or stinging on instillation (4.6%); palpebral edema (2.8%); keratopathy; hypersensitivity reaction; stromal edema; hyperemia; increased intraocular pressure
Valacyclovir[22]	Headache (14%); nausea (15%); vomiting (6%); dizziness (3%); abdominal pain (3%)
Valganciclovir[23]	Neutropenia; thrombocytopenia; diarrhea; nausea, vomiting; abdominal pain; increased SCr; insomnia; peripheral neuropathy; paresthesias; CNS (ataxia, dizziness, seizures, psychosis, hallucinations, confusion, drowsiness); retinal detachment (during treatment of CMV retinitis); hypersensitivity
Zanamivir[24]	Bronchospasm; decline in respiratory function, especially if underlying respiratory disease; nasal or throat irritation or congestion; headache; cough; diarrhea; nausea, vomiting

AV, atrioventricular; BUN, blood urea nitrogen; CMV, cytomegalovirus; CNS, central nervous system; ECG, electrocardiogram; GI, gastrointestinal; SCr, serum creatinine.

Neonatal Herpes

Most neonates acquire herpes from the infected genital secretions of the mother at delivery, and most cases are caused by HSV-2 virus.[28] The incidence ranges from 1 in 3,000 to 5,000 deliveries per year in the United States. The infection can present in one of three forms: localized to the skin, eye, and mouth (SEM) (45%); encephalitis (30%); or disseminated disease (25%). The effects of neonatal herpes can be devastating, and severe disabilities persist in many afflicted children.[28] With currently available antivirals, the mortality has ranged from 4% in those with CNS involvement to 29% in those with other disseminated disease.[28] Neonatal HSV-1 infections may also be acquired after birth through contact with family members with symptomatic or asymptomatic oral-labial HSV-1 infection or from nosocomial transmission. When the virus is transmitted from the mother, clinical evidence of infection in the neonate usually is present 5 to 17 days after birth. Although skin vesicles are the hallmark of infection, at least one-third to one-half of neonates never have skin lesions.[29] In 70% of patients, the disease may progress from isolated skin lesions to involve other organs, including the lungs, liver, spleen, CNS, and eyes.

Diagnosis can be made by direct fluorescent antibody examination of epithelial cells from the infant or the mother. Examination of the base of a vesicular lesion may show giant cells and intranuclear inclusions, which are characteristic of HSV infections. Serologic test results can support a diagnosis of neonatal herpes.

RISK FACTORS

CASE 79-2

QUESTION 1: S.P., an 18-year-old pregnant woman, was admitted to labor and delivery with premature rupture of the membranes. Four hours later, S.P. vaginally delivered a 2.5-kg baby boy, R.P., who had an estimated gestational age of 33 weeks. Twenty-four hours after delivery, S.P. reported the onset of vesicles in the genital area; she had a history of previous episodes of genital herpes. The last infection was during her first trimester of pregnancy. Is R.P. at risk of developing herpes infection?

R.P. is at risk of acquiring herpes infection because the mother had genital herpes during the first trimester and because he was delivered vaginally rather than by cesarean section.[30] The risk of a newborn acquiring the disease from an infected mother with primary disease is about 35%; that from a mother who has reactivation of disease is 3%.[30]

TREATMENT: ACYCLOVIR

CASE 79-2, QUESTION 2: Ten days after birth, R.P. exhibited poor feeding patterns, irritability, and respiratory distress. Three days later, skin lesions appeared. How should R.P. be treated?

R.P. is manifesting signs of HSV infection and should be treated with antiviral therapy (Table 79-2). The drug of choice for neonatal herpes simplex virus infections is IV acyclovir.[28,29] Vidarabine was the first antiviral agent used in the treatment of neonatal HSV. Because of the drastic reduction in morbidity, it became the standard of therapy to which other antiviral agents were compared. In clinical trials comparing vidarabine with acyclovir, acyclovir was shown to be as effective as vidarabine in infants with SEM involvement, encephalitis, and disseminated HSV infection.[31] Although both agents were equally effective, acyclovir was safer and easier to administer, making it the standard of care for neonatal HSV.

Table 79-2

US Food and Drug Administration (FDA)–Indicated Drugs for Various Viral Infections

Disease	Drug	Dosage (Age Group)	Route	Duration
Herpes encephalitis	Acyclovir (Zovirax)[a]	>12 years: 10 mg/kg every 8 hours	IV	21 days
		3 months–12 years: 20 mg/kg every 8 hours	IV	21 days
Neonatal herpes	Acyclovir (Zovirax)	Birth–3 months: 10–20 mg/kg every 8 hours[a]	IV	14–21 days
Oral-facial herpes (for treatment of recurrent infection)	Acyclovir (Zovirax) Famciclovir (Famvir) Valacyclovir (Valtrex)	Adults: 400 mg 5 × per day Adults: 1,500 mg Adults: 2,000 mg BID	PO PO PO	5 days 1 dose 1 day
Oral-facial herpes[b] (immunocompromised patients)	Acyclovir (Zovirax)	>12 years: 5 mg/kg every 8 hours <12 years: 10 mg/kg every 8 hours	IV IV	7 days 7 days
	Famciclovir (Famvir)	Adults: 500 mg BID	PO	7 days
Herpes zoster[b] (immunocompetent patients)	Acyclovir (Zovirax) Famciclovir (Famvir) Valacyclovir (Valtrex)	Adults: 800 mg 5 × per day Adult: 500 mg every 8 hours Adult: 1,000 mg every 8 hours	PO PO PO	7–10 days 7 days 7 days
Herpes zoster[b] (immunocompromised patients)	Acyclovir (Zovirax)	>12 years: 10 mg/kg every 8 hours <12 years: 20 mg/kg every 8 hours	IV IV	7 days 7 days
Varicella (immunocompetent patient)	Acyclovir (Zovirax)	>40 kg: 800 mg QID >2 years and <40 kg: 20 mg/kg (max 800 mg) QID	PO PO	5 days 5–10 days
Varicella (immunocompromised patients)		>12 years: 10 mg/kg every 8 hours <12 years: 500 mg/m^2 every 8 hours	IV IV	7–10 days 7–10 days
Cytomegalovirus retinitis	Ganciclovir (Cytovene)	5 mg/kg every 12 hours; then 5 mg/kg/day, 7days a week or 6	IV	14–21 days for induction;

(immunocompromised patients)		mg/kg/day, 5 days a week		maintenance
	Cidofovir (Vistide)	5 mg/kg every week for 2 weeks, then every 2 weeks	IV	Maintenance
	Foscarnet (Foscavir)	90 mg/kg every 12 hours; then 90 mg/kg every day	IV	Induction for 2 weeks; maintenance
	Valganciclovir (Valcyte)	900 mg BID; 900 mg every day	PO	Induction for 21 days; maintenance
Influenza A	Amantadine[c] (Symmetrel)	>9 years: 100 mg BID	PO	10 days (treatment), 14–28 days (protection with vaccine), 90 days (protection without vaccine)
		1–9 years: 4.4–8.8 mg/kg/day but <150 mg/day	PO	
	Rimantadine[c] (Flumadine)	>14 years: 100 mg BID	PO	7 days (treatment, not approved for treatment in children) up to 6 weeks for prophylaxis
		1–13 years: 100 mg BID	PO	Up to 6 weeks for prophylaxis
		1–9 years: 5 mg/kg div. every day BID (max 150 mg/day)	PO	
Influenza A and B	Oseltamivir (Tamiflu)	>13 years (or >40 kg): 75 mg BID	PO	5 days (treatment)
		>13 years (or >40 kg): 75 mg every day	PO	10 days (prophylaxis)
				Up to 6 weeks (community outbreaks)
		24–40 kg: 60 mg BID	PO	5 days (treatment)
		16–23 kg: 45 mg BID		
		>1 year–15 kg: 30 mg BID		
		24–40 kg: 60 mg every day	PO	10 days (prophylaxis)
		16–23 kg: 45 mg every day		
		>1 year–15 kg: 30 mg every day		
	Zanamivir (Relenza)	>7 years: 10 mg (2 inhalations) BID	Inhalation	5 days (treatment)
		Adolescent and adult: 10 mg (2 inhalations) every day	Inhalation	10 days (prophylaxis) 28 days (community outbreak)
		>5 years: 10 mg (2 inhalations) every day	Inhalation	10 days (prophylaxis)

Respiratory syncytial virus	Ribavirin (Virazole)	6 g in 300 mL for 12–18 hour/day	Inhalation	3–7 days

[a] FDA-approved dose is 10 mg/kg. Although doses of 15–20 mg/kg have been used, safety has not been established at these doses.

[b] Foscarnet 40 mg/kg IV every 8 hours is recommended for acyclovir-resistant herpes simplex virus or varicella-zoster virus.

[c] Amantadine and rimantadine are no longer recommended as drugs of choice for either prophylaxis or treatment of influenza A.

BID, 2 times day; IV, intravenously; PO, orally; QID, 4 times a day.

Acylovir Administration

CASE 79-2, QUESTION 3: What dosage of acyclovir should R.P. receive?

Although an IV dosage of 30 mg/kg given in three divided doses has been shown to be effective in the treatment of neonatal herpes, the use of 60 mg/kg given in three divided doses is superior in decreasing morbidity and mortality. The higher dose of acyclovir is associated with a higher frequency of hematologic abnormalities, especially neutropenia.[9,32,33] The minimum duration of therapy should be 14 days for neonates with only SEM involvement, whereas longer courses (e.g., 21 days) are indicated in infants with CNS involvement or disseminated disease.[28]

The role of prolonged oral suppressive therapy in newborns with SEM involvement has been investigated.[34,35] Acyclovir, given orally (PO) at 300 mg/m^2 per dose 3 times a day (TID), resulted in a reduction in the recurrences of lesions. Half of these patients developed neutropenia. One patient had lesions resistant to acyclovir.[35] Because the long-term benefits cannot be fully attributed to the use of suppressive acyclovir, suppressive therapy for patients with SEM involvement is not recommended.[35]

Oral-Facial Herpes (Herpes Labialis)

Both primary and recurrent oral-facial HSV-1 infections can be asymptomatic. Gingivostomatitis and pharyngitis are the most common clinical manifestations of a first episode of HSV-1 infection, and recurrent herpes labialis is most commonly caused by reactivated HSV infection. Clinical features include fever, malaise, myalgia, inability to eat, and irritability. Immunocompromised patients with oral-facial herpes have severe pain, extensive lesions, and prolonged viral shedding; thus, they are candidates for antiviral therapy.

Herpes labialis (cold sores) is the most common oral-facial HSV infection. Clinical features include pain or paresthesia and erythematous or papular lesions followed by vesiculation and swelling. These lesions usually crust and heal in a few days. Viral cultures generally are positive within 2 to 3 days. Rapid diagnosis can be made by visualizing viral particles in vesicular fluid with electron microscopy or fluorescent antibody staining of cells from vesicles.

INDICATIONS FOR ANTIVIRAL TREATMENT

CASE 79-3

QUESTION 1: M.K., a 26-year-old man, experienced pain and erythematous skin lesions on his face and around his mouth during a 2-day period after contact with a person with active herpetic lesions. For the next 2 days, significant swelling was noted. He remembers similar episodes in the past. M.K. has no previous history of any other illness. Should he be treated with antiviral drugs?

Most patients with herpes labialis have a self-limiting benign course and the lesions heal within 10 days. Antiviral drugs (e.g., acyclovir, valacyclovir, famciclovir) are indicated only when the patient has a primary infection, an underlying illness, or a compromised immune system that may lead to prolonged illness or dissemination.

M.K. should not receive antiviral therapy. However, acetaminophen or nonsteroidal anti-inflammatory agents (NSAIDs) can be considered for symptomatic relief. Although ice, ether, lysine, silver nitrate, and smallpox vaccine have been used to treat cold sores, no data support their efficacy. Symptomatic treatment with ice or popsicles may also be beneficial.

CASE 79-4

QUESTION 1: P.L., a 16-year-old boy diagnosed with acute lymphocytic leukemia 8 months ago, is now admitted for a bone marrow transplant. Admission laboratory tests reveal that he has antibodies against HSV-1 and that 4 months ago, during a course of chemotherapy, he developed an oral-facial herpes infection. What is the significance of these findings for P.L., who is about to undergo a bone marrow transplant?

Immunosuppressed patients have more frequent and severe mucocutaneous HSV infections. Therefore, IV acyclovir should be considered to suppress the reactivation of oral-facial HSV infections.[36,37] Oral therapy with famciclovir is approved for use in HIV-infected patients,[38] but efficacy in other immunocompromised patients is not yet established.

Antiviral Treatment

CASE 79-4, QUESTION 2: P.L. did not receive antiviral therapy. Two weeks later, he developed malaise and painful oral-mucosal and skin lesions on his face. HSV was identified from the lesion by immunofluorescence. What is the treatment of choice for P.L.?

Acyclovir should be administered IV at 5 mg/kg every 8 hours for 7 days[9] or until the lesions are healed, followed by oral acyclovir 200 mg TID for about 6 months.[26] In patients with marrow transplants and culture-proven recurrent mucocutaneous herpes simplex, oral acyclovir (400 mg 5 times daily for 10 days) is significantly more effective than placebo in reducing pain, virus shedding, new lesion formation, and lesion healing time.[39] Valacyclovir and famciclovir have also been used in the transplant population.[40]

CASE 79-5

QUESTION 1: N.B., a 43-year-old woman, experiences 8 to 10 cold sores a year. These are typically preceded by "colds" or sun exposure. She requests a prescription for acyclovir to prevent cold sores when she feels one coming on. What is the role of antiviral medications in the acute treatment and prevention in immunocompetent patients with recurrent herpes labialis?

Topical agents approved by the US Food and Drug Administration (FDA) for the treatment of recurrent herpes labialis in immunocompetent patients include acyclovir 5% cream (Zovirax), acyclovir 5% and hydrocortisone 1% cream (Xerese), docosanol 10% cream (Abreva), and penciclovir 1% cream (Denavir). Clinical trials demonstrate that each agent modestly decreases healing time of herpes lesions when started at the first sign or symptom of a cold sore.[41–47] Although penciclovir cream may be more effective than acyclovir cream, the benefit is small.[44,45] An advantage of docosanol cream compared with the other agents is its availability without a prescription. The topical agents must be applied within 1 hour of the first sign or symptom of a cold sore and then every 2 hours for 4 days while awake.

Studies evaluating the use of oral antiviral agents have produced conflicting results. In some studies, oral antiviral medications have shown to decrease the duration of pain and healing time in immunocompetent patients. One study demonstrated that oral acyclovir 200 mg 5 times daily for 5 days had no benefit.[48] However, 400 mg 5 times daily for 5 days started within 1 hour of the development of a cold sore significantly decreased duration of pain and healing time in immunocompetent patients.[49] Valacyclovir

---

2 g at the first signs of a cold sore followed by 2 g 12 hours later, and famciclovir 1,500 mg as a single dose showed similar clinical efficacy.[50,51] No studies have directly compared the efficacy of the different oral antiviral medications.[52] Frequency of dosing and cost should be considered when choosing a particular agent.[9,15,22]

Daily suppressive therapy may be recommended in patients with six or more recurrences per year, in patients with frequent infection who do not experience a prodrome, or in patients with severe episodes. In immunocompetent patients with six or more episodes of herpes labialis, oral acyclovir 400 mg twice a day (BID) for 4 months was more effective than placebo in decreasing the number of recurrences.[53] Oral valacyclovir, 500 mg once daily or 1,000 mg once daily, is efficacious in decreasing the number of recurrences.[54] Controlled trials of famciclovir for chronic suppressive therapy of herpes labialis have not been performed.

N.B. should be treated with either a topical antiviral medication or an oral antiviral for the acute episode of herpes labialis. She should be instructed to start treatment as soon as the first sign or symptom of the cold sore appears. If suppressive therapy is desired, N.B. should be treated with oral acyclovir or valacyclovir.

RESISTANCE

The incidence of acyclovir-resistant herpes in patients with herpes labialis is greater in immunocompromised patients compared with immunocompetent patients. Current estimates of HSV resistance in the immunocompromised population are about 5%; some populations, such as bone marrow transplant patients, have a resistance rate approaching 30%.[55,56] IV foscarnet 40 mg/kg every 8 hours is more effective and less toxic than IV vidarabine 15 mg/kg/day in patients with AIDS and mucocutaneous herpetic lesions unresponsive to IV acyclovir.[57] More concerning, however, are the reports of foscarnet-resistant HSV, particularly in the bone marrow transplant population.[58,59] Cidofovir has been used with moderate success in such cases. In patients with recurrent acyclovir-resistant genital herpes, limited evidence suggests that topical imiquimod 5% cream may be effective.[60]

VARICELLA-ZOSTER INFECTIONS

Chickenpox

Chickenpox used to be a common childhood infection, but the incidence has decreased by up to 84% in states with moderate use of the varicella-zoster virus (VZV) vaccine since 1995.[61] This vaccine is now considered a routine childhood vaccine by the American Academy of Pediatrics. Unimmunized adolescents and adults who have not had chickenpox should also be vaccinated. Before the vaccine was available, approximately 4 million cases occurred per year in the United States: 90% of cases occurred in children and adolescents less than 15 years of age with the majority of cases occurring between 1 and 4 years of age.[62] In addition to a decline in cases of chickenpox, complications and mortality have also declined.[63] The population at risk for complications such as pneumonia and encephalitis, because of VZV, include immunocompromised individuals and pregnant women. Children with HIV are at an increased risk of mortality from VZV.[63]

Chickenpox is a contagious disease; the average incubation period is 14 to 16 days. Children are considered contagious from 1 to 2 days before the onset of rash until all vesicles have crusted (usually 4–6 days after the onset of rash).[63]

After household exposure, more than 90% of susceptible individuals become infected. Thus, a history of exposure is useful in making a diagnosis. A smear of cells scraped from the lesions will show multinucleated giant cells. Viruses also can be identified in vesicular lesions by electron microscopy, or antigen can be detected by countercurrent immunoelectrophoresis. Chickenpox is a primary varicella-zoster infection, whereas herpes zoster (shingles) is caused by reactivation of VZV.[63]

CLINICAL PRESENTATION

CASE 79-6

QUESTION 1: A.V., a 10-year-old boy, was admitted to the hospital for evaluation and treatment of possible recurrent chickenpox. According to his mother and his physician, he had a mild case of chickenpox at age 4 years and has not received the vaccine. At admission, A.V. had a 10-day history of progressive vesicular and pustular lesions that began on his neck and spread to his back, trunk, extremities, and face. Although he had been febrile (up to 40.5°C orally) for the past 3 days, his temperature on admission was 37°C. A.V. had episodes of vomiting during the 4 days before admission. On admission, he was alert, cooperative, and well oriented but had overt ataxia with abnormal cerebellar signs. Lesions consistent with VZV infection were extensive and confluent over the face, neck, chest, and back. Stages of lesions varied from tiny thin-walled vesicles with an erythematous base to umbilicated vesicles. Few crusted lesions were present. Blood analysis revealed the following results:

BUN, 9 mg/dL (normal, 5–18 mg/dL; 1.8–6.4 mmol/L)
SCr, 0.2 mg/dL (normal, 0.5–0.8 mg/dL; 44–71 μmol/L)
Serum aspartate aminotransferase, 65 international units/L (normal, 0–34 units/L)
Serum alanine aminotransferase 122 international units/L (normal, 0–34 units/L)

Because of the possibility of cerebellar involvement with VZV infection, therapy with acyclovir 550 mg IV every 8 hours (1,500 mg/m^2/day) was instituted. Oral diphenhydramine was also prescribed for itching, but A.V. required only two doses on the first hospital day.

New lesions were noted on the second day of acyclovir therapy, but by the third day no new lesions appeared and previous lesions were healing. The ataxia improved daily. He was discharged on day 7 with no further complaints of nausea and vomiting. Follow-up serologic evaluation demonstrated a fourfold rise in the optical density for the VZV enzyme-linked immunosorbent assay (ELISA) from day 20 to day 60 after the onset of infection. These results suggested primary VZV infection. Why is the use of acyclovir in A.V. appropriate?

ANTIVIRAL TREATMENT

Neonates, adults, immunocompromised hosts, patients with progressive varicella, and those with extracutaneous complications, benefit from acyclovir therapy. Acyclovir is effective in preventing dissemination of VZV infection, accelerating cutaneous healing, decreasing fever and pain, and reducing mortality.[64,65] A.V. had a prolonged progressive course of varicella and demonstrated an extracutaneous manifestation of varicella infection (e.g., ataxia with abnormal cerebellar signs). Because of the concern of possible cerebellar involvement, the use of IV acyclovir was appropriate in A.V.

CASE 79-7

QUESTION 1: C.J., an 8-year-old boy, developed a case of chickenpox and was kept home from school. Four days later, his 15-year-old brother, K.J., began to exhibit similar symptoms. What is the role of acyclovir in immunocompetent patients with chickenpox? Should C.J. or K.J. be treated with acyclovir?

Three studies in children (2–18 years of age) have shown that oral acyclovir 20 mg/kg (when initiated within 24 hours of disease onset) 4 times a day (QID) for 5 to 10 days accelerates healing and decreases the formation of new lesions, fever, and itching. However, the benefit is modest (usually healing 1 day sooner than placebo) and does not reduce the complications of varicella.[66] Thus, the American Academy of Pediatrics does not consider routine use of acyclovir in healthy children justified, and it is not indicated for C.J.[67]

Adolescents and adults are more likely to develop complications (e.g., pneumonia, encephalitis) than children. Others at higher risk for developing complications include those with chronic cutaneous or pulmonary disease, patients receiving chronic salicylate therapy, and patients receiving short, intermittent, or aerosolized corticosteroid therapy.[67] In these patients, acyclovir therapy may be warranted. Acyclovir 800 mg PO QID for 5 days in adolescents and adults (initiated within 24 hours of disease onset) decreases the number of lesions and reduces time for healing, fever, and itching. The effect of acyclovir on prevention of severe complications is unknown.[68–70] Thus, acyclovir therapy should be considered in those at increased risk of severe chickenpox, e.g., those like K.J. who are older than 14 years or those with chronic respiratory or skin disease.[71] There are no published clinical trials to support the use of famciclovir and valacyclovir in the treatment of chickenpox. However, valacyclovir or famciclovir may be preferred because of the need for less frequent administration for adolescents and adults at risk for moderate-to-severe complications.

SUPPORTIVE TREATMENT

CASE 79-7, QUESTION 2: What is the role of supportive treatment in C.J. and K.J.?

Cool baths and application of calamine or other topical antipruritic agents may decrease itching. Fingernails should be trimmed to avoid scratching and secondary bacterial infections. In severe cases, a systemic antipruritic and antihistamine preparation may be useful because some degree of sedation may be desired. In C.J. and K.J., aspirin should not be used because Reye syndrome has been associated with the use of salicylates in chickenpox or flulike illness (see Chapter 102, Pediatric Pharmacotherapy).

Shingles (Herpes Zoster)

Herpes zoster infections are caused by the reactivation of dormant VZV in the sensory neurons. Reactivation is believed to occur because of waning immunity. The incidence of herpes zoster is higher in immunocompromised patients (e.g., those with HIV or cancer or those receiving immunosuppressive medications), and the incidence of zoster increases with age. It tends to be more severe in the elderly.[72]

Acute herpes zoster infection is characterized by pain, which is described as a deep aching or burning pain. It may be accompanied by excessive sensitivity to touch. Many patients exhibit a rash that presents initially as erythematous patches and progresses to vesicles that crust in 7 to 10 days. By 1 month, the rash is usually gone, but scarring can occur.[72]

Postherpetic neuralgia (PHN) is the most common complication of acute herpes zoster characterized by pain that continues for more than 1 month after the onset of the rash. It is estimated that 10% to 70% of patients experience PHN, and its prevention is important because PHN pain is difficult to treat.[72]

The goal of pharmacotherapy in acute herpes zoster is to inhibit viral replication, to reduce pain and duration of rash. Ultimately, by inhibiting the virus, nerve damage can be prevented and the incidence and severity of PHN can be decreased. Unfortunately, no therapy can prevent all cases of PHN.

The herpes zoster vaccine (Zostavax) significantly reduces the incidence of herpes zoster and the associated resulting PHN (see Chapter 64, Vaccinations).

ANTIVIRAL THERAPY IN IMMUNOCOMPETENT PATIENTS

CASE 79-8

QUESTION 1: E.O. is a 72-year-old, previously healthy man who complains of a burning pain under his left arm for the last 2 days. The pain radiates across his chest. The pain is worse when the area is touched. This morning, he noticed a rash that starts under his arm and continues to his midline. Pertinent laboratory findings include BUN of 15 mg/dL (normal, 8–18) and SCr of 2.0 mg/dL (normal, 0.6–1.2). He has not received the herpes zoster vaccine. A diagnosis of herpes zoster is made. What therapy should be initiated?

Acyclovir is the standard antiviral agent against which new VZV therapies are compared. In immunocompetent patients, oral acyclovir 800 mg 5 times daily for 10 days is moderately beneficial in reducing acute pain during the first 28 days. Acyclovir therapy should be initiated within 72 hours of the onset of the rash. The benefit of acyclovir in reducing PHN and chronic pain is modest at best. Although a number of trials showed no benefit from acyclovir in reducing PHN, a meta-analysis of acyclovir treatment in herpes zoster concluded that acyclovir was effective, but that 6.3 patients would need to be treated to prevent one patient from having PHN 6 months after the outbreak of VZV.[73]

Famciclovir (Famvir) is approved for the treatment of acute herpes zoster infection. Famciclovir is a prodrug and is rapidly absorbed and converted to the active drug penciclovir in the intestine. The bioavailability of famciclovir is greater than acyclovir, resulting in higher concentrations of active drug in the infected cells. In addition, the intracellular half-life (10 hours) of penciclovir allows for less frequent administration.[74] Famciclovir 500 mg TID is as effective as acyclovir 800 mg 5 times a day in reducing the duration of acute pain and healing of the rash.[75] Although famciclovir does not decrease the incidence of PHN, it may reduce the duration of PHN.[76]

To overcome the poor oral bioavailability of acyclovir, valacyclovir (Valtrex), a prodrug of acyclovir, was developed. Valacyclovir is rapidly and extensively absorbed and converted to acyclovir after oral administration. Valacyclovir 1 g TID is as effective as acyclovir 800 mg 5 times a day in terms of reducing rash progression and time to rash healing, and valacyclovir is more effective than acyclovir in relieving zoster-associated pain.[77] Valacyclovir is comparable to famciclovir with respect to decreasing the duration of acute zoster-associated pain and PHN.[78]

E.O. should be started on either acyclovir, famciclovir, or valacyclovir. Famciclovir or valacyclovir may be preferred because adherence with a 3-times-daily regimen will likely be better than with acyclovir, which must be administered 5 times a day. Therapy should be initiated within 72 hours of the rash onset and continued for 10 days; the duration of therapy for famciclovir and valacyclovir is 7 days. Although therapy may not prevent PHN, it may decrease the duration of pain. Because these agents are renally eliminated, the dosage should be adjusted based on E.O.'s reduced creatinine clearance (Table 79-3).

For acute illness, E.O. may require pain control with medications such as nonsteroidal anti-inflammatory agents, opioids, or tramadol.[91,92] In addition, E.O. should be counseled to keep the area of the rash clean and dry and to avoid topical antibiotics. If the rash worsens or fever develops, he should contact his health care professional.

Table 79-3

CASE 79-8, QUESTION 2: Should E.O. receive a corticosteroid to treat or prevent the pain associated with herpes zoster?

The decision to use corticosteroids, such as prednisone or prednisolone, remains controversial.[93] A number of studies have examined the effect of steroids on pain during acute neuralgia and on the development of PHN. Early studies revealed that steroids are effective for both acute pain and PHN, but these studies were small and uncontrolled, and used various corticosteroid regimens. Most studies suggest relief of the acute pain but no decrease in PHN.[94–97] Because of recent studies demonstrating a lack of benefit in preventing PHN, the theoretical concerns of herpes zoster dissemination, the development of secondary bacterial infections, and the beneficial effects of antiviral agents such as acyclovir, famciclovir, and valacyclovir for acute pain, corticosteroids should not be used in E.O.

CASE 79-8, QUESTION 3: Two months after the onset of the rash, E.O. continues to complain of pain. A diagnosis of PHN is made. What FDA-approved treatments for PHN should be prescribed for E.O.?

Although many different agents have been studied, the only FDA-approved treatments for PHN are topical capsaicin cream or gel, capsaicin patch 8% (Qutenza), topical lidocaine 5% patches (Lidoderm), and oral gabapentin (Neurontin) and pregabalin (Lyrica). Capsaicin depletes substance P, a mediator that transmits pain from the periphery to the CNS. The largest double-blind, placebo-controlled trial of capsaicin evaluated 143 patients with PHN for at least 6 months.[98] After 6 weeks of treatment with capsaicin 0.075% cream, pain scores were reduced in 21% and 6% of the capsaicin and placebo groups, respectively. After the double-blind phase of the study ended, a subset of patients continued to use capsaicin cream for up to 2 years, and most patients experienced prolonged pain relief.[98] Capsaicin should be applied 3 or 4 times per day. Qutenza is a capsaicin patch, which is applied by a health care professional. The patch is applied for 1 hour and cannot be repeated more frequently than every 3 months. Lidocaine 5% patches have only been compared with placebo and have been shown to relieve pain for 4 to 12 hours after administration. Either capsaicin cream or gel or lidocaine patches can be considered as a first-line option for E.O. A common adverse effect is a burning sensation after application of capsaicin, which is intolerable in up to one-third of patients. The burning sensation usually lessens with continued use.

If lidocaine patches are prescribed, E.O. should be instructed to apply up to three patches to the painful area. Patients should be instructed to wear the patches for a maximum of 12 hours a day, and proper disposal of used patches should be emphasized. Even a used patch contains a large amount of lidocaine, and small children or pets could suffer serious consequences from chewing or swallowing a used patch.[99]

Pregabalin is approved for the treatment of PHN, but it is associated with a greater risk of adverse effects. Pregabalin binds to a subunit of calcium channels, thereby decreasing calcium influx at nerve terminals and reducing the release of several neurotransmitters, including glutamate, norepinephrine, and substance P.[100] In clinical trials, dizziness was experienced by 29% of patients treated with pregabalin compared with 9% of placebo-treated patients; somnolence was noted in 22% of patients who received pregabalin compared with 8% of placebo-treated patients. Dizziness and somnolence usually occur soon after the pregabalin is started and is dose dependent.[100]

Other agents that have been used in the treatment of PHN include tricyclic antidepressants (e.g., amitriptyline, desipramine) and opioids.[101]

ANTIVIRAL THERAPY IN IMMUNOCOMPROMISED PATIENTS

CASE 79-9

QUESTION 1: R.F. is a 68-year-old woman with a chief complaint of vesicles on her face associated with severe pain. She has a history of polymyalgia rheumatica and possible temporal arteritis with headaches that are responsive to steroids. She had been having increasing headaches on the right side of her forehead 5 days before admission. Two days before admission, her family physician increased the dosage of prednisone from 30 to 60 mg/day. Vesicles developed on her face 1 day before admission. She was admitted for pain control and diagnosed with herpes zoster infection. Six hours after admission, R.F. began having visual hallucinations, hearing noises, and talking to herself. A lumbar puncture was performed with the following results:

WBCs, 3 (2 lymphocytes and 1 monocyte)
RBCs, 3
Protein, 84 mg/dL
Glucose, 86 mg/dL

VZV was isolated from the CSF and IV acyclovir was started at a dosage of 10 mg/kg every 8 hours. Why is antiviral therapy indicated in R.F.? Should her prednisone be continued or discontinued?

Antiviral therapy is indicated for R.F. Acyclovir may halt the progression of acute herpes zoster infection in immunocompromised hosts such as R.F., who has been taking large doses of corticosteroids.[102]

IV acyclovir 10 mg/kg every 8 hours is effective in severely immunocompromised patients. Alternatively, in less severely immunocompromised patients, oral therapy with acyclovir 800 mg 5 times a day, valacyclovir 1,000 mg TID, or famciclovir 500 mg TID, along with close monitoring, can be used.[103] Antiviral therapy is associated with more rapid clearance of the herpes zoster virus from vesicles. Acyclovir has little to no benefit in resolution of pain or prevention of PHN.[102] Initial data indicate that famciclovir or valacyclovir are effective in severe herpes zoster infection in an immunocompromised host.[104,105]

Systemic corticosteroids are of unproven usefulness and may slow the healing of lesions. Therefore, if possible, R.F.'s prednisone should be slowly tapered.

Acyclovir Toxicity

CASE 79-9, QUESTION 2: On the fourth day of acyclovir therapy, R.F. developed severe nausea and vomited 3 times. The laboratory data showed a BUN of 45 mg/dL and SCr of 3.2 mg/dL (baseline BUN, 10 mg/dL and SCr, 1.0 mg/dL). Why must R.F.'s acyclovir dosage be altered?

Nausea and vomiting have been reported with acyclovir therapy in patients with herpes zoster infections.[9] Similarly, elevations of SCr and BUN can occur in association with acyclovir therapy. This may be secondary to acyclovir crystallization in the renal tubules, particularly when fluid intake is inadequate (Table 79-1). Because R.F.'s creatinine clearance is between 10 and 25 mL/minute per 1.73 m^2, the acyclovir dosage interval should be extended to 24 hours. Every effort should be made to maintain adequate hydration for the duration of acyclovir therapy. (See Table 79-3 and Chapter 2, Interpretation of Clinical Laboratory Tests, for creatinine clearance calculation.)

INFLUENZA

Influenza is an acute infection caused by the virus of the Orthomyxoviridae family. Epidemics of influenza are usually caused by the type A virus; type B virus is generally associated with more sporadic infection. Infection is transmitted by the inhalation of virus-containing droplets ejected from the respiratory tract of a person with influenza. Influenza can be spread by direct contact, large droplets, or items recently contaminated by nasopharyngeal secretions. The incubation period is typically 2 days (range, 1–4 days).

Influenza A viruses are classified into subtypes of hemagglutinin (H) and neuraminidase (N) surface antigens. Three subtypes of hemagglutinin (H1, H2, H3) and two subtypes of neuraminidase (N1, N2) have caused influenza in humans. Infection with a virus of one subtype may confer little or no protection against viruses of other subtypes. In addition, significant antigenic variation (antigenic drift) within a subtype may occur with time. Thus, infection or vaccination with one strain may not protect against a distantly related strain of the same subtype. This is why major epidemics of influenza continue to occur, and influenza vaccines must be reformulated each year with the most likely viral strains to maximize vaccine benefit.[106]

The influenza vaccine is indicated for all individuals 6 months of age or older. However, there are a number of populations for which vaccination is vital. Persons at highest risk for influenza infection (Table 79-4) should receive the influenza vaccine each year. Two influenza virus vaccines are currently available, a trivalent vaccine which contains two type A strains and one type B strain, and a quadrivalent vaccine which contains two strains of type A and type B.[107] At this time, no recommendations exist regarding which vaccine is preferred in specific populations. Additionally, a high-dose influenza virus vaccine is available which is indicated for patients 65 years or older. The high-dose vaccine formulation contains 4 times the amount of antigen contained in other influenza vaccine products. The higher strength vaccine is intended to illicit a stronger immune response in the elderly, a population known to have a suboptimal response to the standard-dose influenza vaccine. Early trials with the higher strength vaccine found the high-dose vaccine was 24.2% more effective in preventing influenza in adults 65 years of age and older relative to a standard-dose vaccine.[108] Lastly, an intradermal influenza vaccine is injected subcutaneously rather than intramuscularly. The intradermal vaccine requires a smaller gauge needle for administration and less antigen to be as effective as the regular flu vaccine. It is indicated in adults 18 to 64 years of age.[109]

Table 79-4

Persons Who Should Receive the Influenza Vaccine[97]

- All persons 6 months of age or older
- Nursing home or chronic care facility residents
- Children and adults with chronic pulmonary or cardiovascular disease
- Children and adults who have required medical follow-up because of chronic metabolic diseases (e.g., diabetes mellitus), renal dysfunction, hemoglobinopathies, or immunosuppression (as a result of medications or diseases such as HIV)
- Children and adults who are at risk for aspiration (e.g., cognitive dysfunction, spinal cord injuries, seizures)
- Children (6 months–18 years) receiving long-term aspirin therapy
- Women who will be pregnant during influenza season
- Health care workers
- Household members of persons in high-risk groups (including contacts of infants and children 0–59 months)

The efficacy of the influenza vaccine depends on the similarity of the components of the vaccine to the circulating viruses that year and the immunocompetence of the host. If there is a good match with the circulating viruses, the vaccine can prevent illness in approximately 70% to 90% of healthy adults and children. The vaccine is effective in preventing hospitalization and pneumonia in approximately 30% of elderly persons living in the community and in 40% of elderly persons residing in nursing homes.[110] Despite the lower efficacy, vaccination is still associated with less severe illness and fewer complications in vaccinated individuals.

Individuals at high risk for transmission to patients include physicians, nurses, and other personnel in both hospital and ambulatory settings; employees of nursing homes and chronic care facilities; providers of home care services; and household members, including children. It is vital that all the above individuals should be vaccinated annually. However, considering the morbidity and mortality associated with influenza, all individuals should receive an annual influenza vaccination.

The optimal time for vaccine administration is between mid-October and mid-November because influenza activity peaks between late December and early March in the United States. Vaccinating an individual too early in the season could result in waning antibody concentrations before the influenza season is over. However, influenza vaccine should be offered throughout the influenza season, even if outbreaks of influenza have already been documented in the community.[107]

Because the parenteral influenza vaccine is an inactivated vaccine and contains no infectious viruses, it cannot cause influenza. The most common adverse effect is soreness at the administration site lasting for up to 2 days.[111] Fever, malaise, myalgia, and other systemic reactions occur infrequently; these may develop within 6 to 12 hours after the vaccine is given and persist for 1 to 3 days.[110,111] Immediate hypersensitivity to egg protein (hives, angioedema, allergic asthma, or systemic anaphylaxis) rarely occurs. Persons with anaphylactic hypersensitivity and those with acute febrile illness should not be given the vaccine. However, minor illnesses with or without fever are not contraindications for the influenza vaccine, particularly in children with a mild upper respiratory tract infection or allergic rhinitis. When the vaccine is contraindicated, a neuraminidase inhibitor (oseltamivir or zanamivir) should be used for prophylaxis.[107] Amantadine and rimantadine are no longer recommended for prophylaxis of influenza because of widespread resistance in the United States.[107]

Clinically, it is impossible to differentiate between influenza A and B. Definitive diagnosis can be made by isolating the virus from throat washings or sputum and by a significant increase in antibody titers during the convalescent period.

Clinical Presentation

CASE 79-10

QUESTION 1: K.B., a 40-year-old woman, comes into the pharmacy claiming she has "the flu." She recently started a new job and is afraid she will lose her job if she misses too many days from work. What questions would you ask her to differentiate the common cold from an influenza infection?

Although it can be difficult to differentiate the common cold from influenza, there are some clues that may suggest one viral infection from the other. Influenza infections typically occur from December through March in the United States. Patients with influenza generally experience more systemic symptoms, such as fever higher than 102°F, headache, myalgia, and cough. Rhinorrhea, nasal congestion, and sneezing are more pronounced in patients with the common cold. Sore throat can occur with both a cold and the flu. Bacterial sore throat (e.g., strep throat) is somewhat differentiated from a viral sore throat in that a viral sore throat usually has a slower onset and the throat pain is less severe. Lymph nodes are only slightly enlarged and not tender in a viral sore throat, whereas with a bacterial sore throat, lymph nodes are large and tender.[112]

K.B. should be questioned about her symptoms and exposure to ill contacts, and investigation into whether influenza has been documented in the community should be performed to help differentiate an influenza infection from the common cold.

Treatment

CASE 79-10, QUESTION 2: K.B. describes symptoms consistent with an influenza infection for the past 24 hours. What treatment options exist for the treatment of influenza? Why is she a candidate for a neuraminidase inhibitor agent such as zanamivir or oseltamivir?

Persons with suspected or confirmed influenza virus infection who are at high risk of developing complications (e.g., those with preexisting cardiac or pulmonary disease, unvaccinated infants and children, elderly, immunocompromised) may benefit from antiviral therapy if started within 48 hours after the onset of symptoms. Treatment is recommended regardless of influenza vaccination status and severity of illness in all patients who develop symptoms of influenza and who require hospitalization. Treatment should be considered in outpatients at high risk of complications with illness that is not improving or in patients who request antiviral therapy within 48 hours of onset of symptoms. Therapy will shorten the duration of illness and decrease the risk for transmission to others in close contact with persons at high risk of complications secondary to influenza infection. The benefits are less clear in patients who have had symptoms longer than 48 hours.[113]

The neuraminidase inhibitors, zanamivir (Relenza), oseltamivir (Tamiflu), and peramivir (Rapivab) are active against influenza A and B. These agents work by selectively inhibiting the enzyme neuraminidase, an enzyme necessary for viral replication and spread. Oral Oseltamivir is currently indicated for the prevention and treatment of influenza in patients 1 year of age and older; oral zanamivir is indicated for the prevention of influenza in patients 7 years of age and older and for the treatment of influenza in patients 5 years of age and older.[18,24] Peramivir, a parenteral formulation, is indicated in adults, greater than 18 years of age, and in patients who cannot tolerate or absorb orally administered oseltamivir or inhaled zanamivir.[114]

Zanamivir is available as an oral powder for inhalation. For the treatment of influenza infection in adults, 10 mg (two inhalations) BID for 5 days should be used. Patients should inhale two doses, separated by at least 2 hours, on the first day and then two doses, separated by 12 hours, on days 2 through 5.[24] Bronchospasm after use can occur, and if bronchodilators are also prescribed, the bronchodilator should be used before zanamivir.[24] Proper use of the delivery system (Rotadisk/Diskhaler) is important, and thus patients should be instructed by the pharmacist on proper delivery technique, with a demonstration device.

Oseltamivir is pharmacologically related to zanamivir but has significantly better oral bioavailability, allowing oral dosing. It is approved for children over 1 year of age and for adults. The dosage of oseltamivir for the treatment of influenza in adults is 75 mg BID for 5 days.[18] Oseltamivir is available as a suspension with pediatric dosing recommendations. As with zanamivir, treatment with oseltamivir must be started within 48 hours of the onset of symptoms. Common side effects include nausea, vomiting, and headache.[18] Of concern is that oseltamivir-resistant influenza has been reported.[115] In addition, there are reports, predominantly in children, of self-injury and delirium after the administration of oseltamivir.[116]

Peramivir is dosed at 600 mg once and is administered intramuscularly or intravenously as an infusion over 15 to 30 minutes. As the agent was primarily studied in patients with influenza A and moderate disease, efficacy is unknown for patients infected with influenza B or patients with severe infection requiring hospitalization. The most common side effect is diarrhea; however, severe dermatologic reactions and abnormal behaviors have been reported with its use.[114]

Resistance to amantadine and rimantadine has increased dramatically in recent years; consequently, these agents are no longer recommended for the routine prevention or treatment of influenza infections.[117]

When administered within 48 hours of onset of illness, zanamivir and oseltamivir reduce influenza symptoms by approximately 1 day.[118–120] Information regarding the effectiveness of the neuraminidase inhibitors in preventing serious complications of influenza, such as pneumonia or worsening of chronic diseases, is limited.[107] Considering the causative agent is unknown and symptoms have been present for only 24 hours, K.B. may benefit from a neuraminidase inhibitor. Oral oseltamivir is easier to administer than inhaled zanamivir, and the patient has no reason to not tolerate this drug. Although oseltamivir will not cure influenza, it may reduce the severity and duration of symptoms by about 1 day. She should be treated with a 5-day course of oseltamivir.

CASE 79-11

QUESTION 1: J.T., a 74-year-old man, is brought to the ED from a nursing home with chief complaints of fever (103°F), shaking chills, cough, headache, malaise, anorexia, and photophobia. He has been ill for the past 48 hours but is much worse this evening. On physical examination, he appeared flushed, his skin was hot and moist, and he was having difficulty breathing. Vital signs included blood pressure, 150/90 mm Hg; pulse, 108 beats/minute; respiratory rate, 22 breaths/minute; and temperature, 103°F. Rales were audible on auscultation of both lungs. A chest roentgenogram showed bilateral infiltrates but no consolidation. Blood gas studies showed significant hypoxia, with a Pao_2 of 50 mm Hg and a $Paco_2$ of 50 mm Hg. J.T.'s medical history was significant for chronic bronchitis and a stroke 16 months ago. Blood, sputum, and urine cultures were obtained, and J.T. was started on antibiotics (ceftriaxone 1 g IV every 24 hours and azithromycin 500 mg IV every 24 hours). Gram stain of the sputum sample showed many WBCs but no bacteria. He was started on oxygen therapy at 4 L/minute via nasal cannula. Twenty-four hours later, his respiratory symptoms worsened, and his arterial blood gases deteriorated slightly (Pao_2, 40 mm Hg; $Paco_2$, 55 mm Hg). J.T. was intubated, and a sputum sample was obtained and sent to the virology laboratory. Three days later, influenza A virus was isolated from the sputum. Blood, urine, and sputum cultures were all negative for bacterial pathogens. Why is this presentation consistent with influenza infection? Is antiviral treatment appropriate in J.T.?

Although symptoms of influenza may vary depending on age, most patients with influenza A have an abrupt onset of fever, chills, cough, and headache. In elderly patients such as J.T. and those

---

with underlying diseases, the course of influenza can worsen quickly, and patients are more likely to require hospitalization.

Antiviral therapy in J.T. is inappropriate. None of the antiviral agents has been studied in patients presenting with symptoms after 48 hours of onset. In addition, the antiviral agents have shown efficacy only in uncomplicated influenza.[107]

Prevention

INFLUENZA VACCINES

CASE 79-11, QUESTION 2: During the next 3 weeks, two other nursing home patients develop influenza A infections. What measures should be taken to prevent a further outbreak of influenza among other residents?

The nursing home residents and staff should receive influenza vaccine plus chemoprophylaxis with oseltamivir or zanamivir. The Centers for Disease Control and Prevention (CDC) recommends immunization of all individuals 6 months of age or older, and especially those in high-risk groups, primarily all individuals who are at high risk for influenza-related complications and their household contacts (Table 79-4).[107] Second in priority are otherwise healthy adults 50 years of age or older and children with chronic metabolic diseases severe enough to warrant regular follow-up during the preceding year. Any child younger than 9 years in whom the vaccine is indicated requires two doses of the vaccine for optimal effectiveness. The first dose should be administered as soon as the vaccine becomes available, if possible by October, and the second dose is given before influenza infection is present in the community. Vaccination should continue throughout the season, and can be given as late as February or March, depending on the duration of the influenza season. However, the efficacy of influenza vaccine is incomplete (70%).[120] Therefore, oseltamivir or zanamivir should be used in high-risk individuals who may not develop an adequate antibody response (e.g., patients with advanced HIV infection, residents of nursing homes) to supplement the protection by vaccine.[108,113]

A live, attenuated influenza vaccine (FluMist) is an option for healthy, nonpregnant individuals between the ages of 2 and 49 years. In clinical studies with matched influenza strains, live, attenuated influenza vaccine was approximately 87% effective in preventing influenza in children and provided 85% efficacy in adults.[121,122] Advantages of the intranasal route of administration include ease of administration and patient acceptability of an intranasal preparation compared with an intramuscular (IM) injection. However, because the vaccine is live, viral shedding can occur for 2 or more days after vaccination. Consequently, patients who are immunosuppressed and close contacts of patients who are severely immunocompromised (including health care workers who care for them) should not receive the live vaccine. Others who should not receive the live vaccine include patients with asthma or other chronic disorders of the pulmonary or cardiovascular systems, those with chronic metabolic diseases such as diabetes, renal dysfunction, or hemoglobinopathies, and children or adolescents who are receiving aspirin or other salicylates.[107]

OSELTAMIVIR AND ZANAMIVIR

Analysis of clinical trials of oseltamivir in the prevention of influenza showed a decreased incidence of laboratory-confirmed influenza: 4.8% in the placebo group and 1.2% in the treatment group.[123] The incidence of influenza in a skilled nursing facility was 4.4% in the placebo group and 0.4% in the oseltamivir group. In addition, oseltamivir lowered the rate of infection in patients exposed to influenza at home from 12% to 1%. Zanamivir has also been found to be effective in preventing infection.[124,125]

Comparative studies between neuraminidase inhibitors have not been published. Considering that oseltamivir is available in an oral formulation, it is easier to administer in nursing home patients compared with zanamivir, which requires proper use of the delivery device and a coordinated inspiratory effort.

RESPIRATORY SYNCYTIAL VIRUS INFECTIONS

Respiratory syncytial virus (RSV) causes bronchiolitis and bronchopneumonia in infants younger than 2 years. More than one-half of affected infants are infected in the first 2 years of life. Of these infants, approximately 1% to 2% will require hospitalization.[126] Children who are severely premature, immunocompromised, or with underlying congenital heart disease or lung disease may be at increased risk of mortality because of RSV.[127] Patients with RSV infection before 3 years of age are at increased risk of wheezing and asthma during childhood.[128]

RSV infections usually occur in the winter. The chest radiograph and blood gases are often abnormal, and the virus can be isolated in the nasopharyngeal secretions.

Clinical Presentation and Ribavirin Therapy

CASE 79-12

QUESTION 1: J.R., a male 6-month-old infant who is lethargic, tachypneic, and cyanotic, is brought to the ED. J.R.'s medical history is significant for congenital HIV. He has a fever (102°F), his breathing is labored, and wheezing is audible on expiration. The chest roentgenograms reveal a flattened diaphragm and hyperinflated lung parenchyma. Because of hypoxemia and hypercarbia, J.R. is placed on ambient oxygen to maintain the alveolar oxygen pressure at greater than 60 mm Hg. RSV is present in the respiratory secretions. What therapy is indicated for J.R.?

The goal of RSV therapy is to increase oxygen saturation and decrease airway resistance in patients such as J.R.[129] Treatment of RSV is highly individualized, depending on the presenting signs and symptoms and associated comorbidities. Oxygen is first-line therapy. Although decreases in airway resistance are often achieved with the use of bronchodilators or corticosteroids in other conditions, such as asthma, they have not proven to be effective in the treatment of bronchiolitis.[130,131] Hypertonic saline, administered as a nebulized solution, is beneficial in increasing mucociliary clearance.[130] Infants and children admitted for bronchiolitis with an expected length of stay (LOS) of at least 3 days (moderate-to-severe presentation) may experience a shortened LOS by 1 day when prescribed 3% nebulized saline.[131] Adverse reactions include wheezing and excessive secretions.

Ribavirin (Virazole) is active against many DNA and RNA viruses, including RSV. However, its clinical benefit remains controversial. Early studies with ribavirin showed significant clinical improvement compared with placebo in both healthy children and those with underlying disease.[132] These studies reported benefit in terms of clinical recovery and improvement in arterial oxygenation. Subsequent studies found ribavirin to be ineffective in patients with a variety of risk factors.[133,134] Consequently, the routine use in previously healthy infants and children has not been clearly established. Whether ribavirin decreases the long-term sequelae and severity of illness in high-risk groups (including premature infants, patients with bronchopulmonary dysplasia, congenital heart disease, cystic fibrosis, and immunodeficiency) has not been

---

determined.[135] Current recommendations include consideration for use of ribavirin in infants at risk for severe life-threatening infection.[135] Because J.R. has an underlying immunodeficiency, ribavirin may be considered if J.R.'s condition worsens.

ADMINISTRATION OF RIBAVIRIN

CASE 79-12, QUESTION 2: How is ribavirin administered, and what precautions should be taken during drug administration in J.R.?

Ribavirin is administered as an aerosol through a collision generator that generates particles small enough (1–2 µm wide) to reach the lower respiratory tract. The concentration of the ribavirin solution in the reservoir is 20 mg/mL (6 g in 300 mL of sterile water). The dose is administered over the course of 12 to 18 hours, although in nonventilated patients, 2 g during 2 hours TID (using a 60-mg/mL solution) has been successfully used.[132] Ribavirin therapy is continued for 3 to 7 days.[19]

Ribavirin is approved for use in patients requiring mechanical ventilation. However, ribavirin is hygroscopic, and aerosol particles can deposit in the tubing and around the expiratory valve of a ventilator. The precipitated drug can obstruct the expiratory valve and alter the peak end-expiratory pressure.[19] Ribavirin has been safely used in such patients,[136,137] but close monitoring of respiratory therapy is advised to prevent this problem. In addition to the inspection of tubing, modifications of standard ventilatory circuits have been suggested.[19]

ADVERSE EFFECTS

CASE 79-12, QUESTION 3: What are the important adverse effects of ribavirin?

The most common adverse effects of ribavirin are rash, initial mild bronchospasm, and reversible skin irritation.[138] Although long-term follow-up data are limited, a study evaluating the effects of ribavirin in patients 1 year after administration showed a reduction in the incidence and severity of reactive airway disease, as well as in hospitalizations related to respiratory illness.[139] Further long-term evaluation is still necessary.

Ribavirin is contraindicated in women who are or may become pregnant during exposure to the drug. Although there are no human data, ribavirin has been found to be teratogenic or lethal to embryos in nearly all animal species in which it has been tested. Teratogenesis was evident after a single oral dose of 2.5 mg/kg in hamsters and after daily oral doses of 10 mg/kg in rats. Malformation of the skull, palate, eye, jaw, skeleton, and GI tract have been documented in animals. Ribavirin has reduced the survival of fetuses and offspring of animals tested. It is lethal to rabbit embryos in daily oral doses as small as 1 mg/kg. There are no studies that address teratogenicity in humans, but hospital personnel who are pregnant or may become pregnant should avoid exposure to this drug.[19]

It is important to consider the environmental effects of ribavirin on the personnel involved with its administration. One study found no detectable plasma or urine concentrations of ribavirin in 19 nurses, whereas another reported its presence in the RBCs of a nurse caring for a patient who received ribavirin via oxygen tent.[140] The ribavirin concentration in the air was highest when it was administered via oxygen tent, followed by mist mask, and was lowest after administration via endotracheal tubes of mechanically ventilated patients. This has led to several recommendations: (a) ribavirin aerosol should be administered solely via endotracheal tube of mechanically ventilated patients in a closed filtered system[126]; (b) children receiving ribavirin should be placed in a containment chamber equipped with a high-efficiency particulate air filter exhaust in an isolation room with negative air pressure[19]; (c) disposable full-body coverings and either a powered air-purifying respirator or disposable particulate respirator should be made available to all health care personne[140]; and (d) men and women planning to have children should not care for patients receiving ribavirin via oxygen tents.[140] Valeant Pharmaceuticals markets an aerosol delivery system for oxygen and ribavirin that decreases the liberation of ribavirin into the environment.[19]

Prevention

CASE 79-13

QUESTION 1: S.N. is a 7-month-old boy born prematurely at 27 weeks' gestation. He has chronic lung disease of prematurity (CLD) and uses oxygen at home. RSV season will begin next month. What treatments to prevent RSV infection are available? Why is S.N. a candidate for such treatment?

Palivizumab (Synagis), a humanized monoclonal antibody made from recombinant DNA, is active against RSV and is indicated for children at risk of severe RSV respiratory tract infections (e.g., infants with CLD or a history of premature birth before 29 weeks' gestation). The efficacy of palivizumab has been demonstrated in children with a history of prematurity or CLD.[141] Children receiving monthly IM injections of palivizumab for 5 months during RSV season had a reduction in hospitalizations and intensive care admissions for RSV disease. Palivizumab has replaced the use of RSV-immunoglobulins in infants because it is easier to administer (IM vs. IV), does not interfere with the response of live vaccines such as measles–mumps–rubella or varicella vaccine, and is not likely to transmit blood-borne diseases because it is a synthetic product rather than one derived from human blood.[142]

Based on S.N.'s age and his CLD, he is a candidate for palivizumab therapy.[130]

PALIVIZUMAB DOSAGE AND ADMINISTRATION

CASE 79-13, QUESTION 2: How are the doses of palivizumab calculated, and how should it be administered?

The dose of palivizumab is 15 mg/kg given IM. The first dose is given before the start of the RSV season, and then monthly doses are given for a total of 5 months. In the Northern Hemisphere, the RSV season is typically November through April.

HANTAVIRUS

Infections

Rodents are the primary reservoir hosts of Hantavirus, and in the United States the deer mouse (Peromyscus maniculatus) is the main reservoir. These viruses apparently do not cause illness in the reservoir hosts, but infection in humans occurs when infected saliva, urine, and feces produced by the rodent are inhaled as aerosols. Most patients recall exposure to rodents or rodent feces within 6 weeks of the onset of illness.[143] Person-to-person transmission has not been documented.

The case definition includes clinical evidence of (a) febrile illness characterized by unexplained adult respiratory distress syndrome (ARDS) or acute bilateral pulmonary interstitial infiltrates, or (b) an autopsy finding of noncardiogenic pulmonary edema, resulting from an unexplained respiratory illness. In addition, laboratory evidence consists of (a) a positive serology (i.e., presence of hantavirus-specific immunoglobulin [Ig] M

or rising titers of IgG), (b) positive immunohistochemistry for hantavirus antigen in a tissue specimen, or (c) positive PCR for hantavirus RNA in a tissue specimen.[144] Hantavirus infection can cause three different clinical diseases: hemorrhagic fever with renal syndrome, nephropathia epidemica, and hantavirus pulmonary syndrome (HPS). Hemorrhagic fever with renal syndrome and nephropathia epidemica occur in Asian and European countries. HPS occurs only in the Western Hemisphere, including North America.[145] From 1993 to 2013, 606 cases of HPS were reported in the United States, with 36% of the cases resulting in death.[146] Most have occurred in the southwestern United States during spring and summer.

Clinical Presentation

The clinical features of patients with HPS include fever, myalgia, headache, and cough. Abdominal pain, nausea, or vomiting may also be present. The physical examination has been unreliable. Laboratory abnormalities may include leukocytosis, thrombocytopenia, and hypoalbuminemia. The chest radiograph may initially be normal, but rapid disease progress may show bilateral infiltrates and ARDS. Other viral pneumonias do not typically progress to ARDS as rapidly as hantavirus infections. Because of the nonspecific signs and symptoms, some patients may be misdiagnosed as having influenza.[147]

Treatment

Supportive treatment is important. Oxygen therapy and mechanical ventilation may be necessary. Hypotension can be treated with vasopressor agents and judicious use of IV crystalloids (i.e., 0.9% NaCl) to prevent worsening of pulmonary edema. Universal precautions and respiratory isolation should be instituted.[145]

There is no FDA-approved drug to treat hantavirus infections. Based on one study in 242 patients, IV ribavirin was more effective than placebo in reducing morbidity (oliguria and hemorrhage) and mortality. IV ribavirin was given as a loading dose of 33 mg/kg, followed by 16 mg/kg every 6 hours for 4 days, and 8 mg/kg every 8 hours for the next 3 days.[148]

Two other clinical trials, however, did not show similar clinical efficacy in the treatment of HPS. One open-label trial conducted by the CDC showed a mortality rate of 47% in patients who received ribavirin compared with 50% to those who did not.[147] In addition, a small trial conducted at the National Institutes of Health could not demonstrate any benefit from ribavirin.[149]

WEST NILE VIRUS

West Nile virus (WNV) was first identified in the United States in 1999 in New York City. Since then, the virus has had rapid geographic expansion and has infected individuals in all states in the continental United States.[150] Although WNV normally occurs in tropical climates, the increase in international travel and changes in weather patterns have led to its spread.

WNV is a member of the Flaviviridae family. Culicine mosquitoes (including Culex pipiens, Culex restuans, and Culex quinquefasciatus) are the vectors, and they infect both birds and humans.[151] Infection with the virus involves direct inoculation by the infecting mosquito. Birds are reservoir hosts. WNV can infect a number of vertebrates, including horses. Transmission usually occurs from a mosquito bite; however, reports indicate that transmission of the infection has occurred through transfusions, organ transplantation, placental transfer, and via breast milk.[152] Because of the seasonal variations in the life cycle of the mosquito, cases are most commonly seen during the summer and early fall.

Diagnosis is usually made by high clinical suspicion and laboratory tests. WNV can cause a wide range of illness, from an asymptomatic disease to West Nile fever to encephalitis or meningitis. Mortality is low except in the neuroinvasive forms of the infection. Mortality rates in the elderly, particularly those older than 70 years, can be 9 times higher than in the general population.[153] The CDC laboratory criteria for diagnosis of WNV include (a) isolation of the WNV antigen or genomic sequence from a tissue, blood, CSF, or other body fluids; (b) WNV IgM antibody in a CSF sample; (c) a fourfold rise in the antibody titer to WNV; and (d) demonstration of an IgM or rising titers of IgG to WNV in a single serum sample.[154]

Clinical Presentation

CASE 79-14

QUESTION 1: A.G. is an 84-year-old woman. She is very active and runs the yearly flower festival in the community. She was brought to the ED by her granddaughter, who found her at home, confused and complaining of a headache, fatigue, and increasing muscle weakness. She has a temperature of 103°F, and her Mini-Mental Status Examination score is 21 of 30. She has decreasing muscle strength and an erythematous, macular, papular rash on her arms and legs. The complete blood count and electrolytes are normal, with the exception of slightly decreased sodium. The CSF reveals increased WBCs, increased protein, normal glucose, and positive IgM antibody to WNV. A CT scan shows no abnormalities. What signs and symptoms are indicative of WNV encephalitis?

Acute signs and symptoms of WNV include sudden onset of fever, anorexia, weakness, nausea, vomiting, eye pain, headache, altered mental status, and stiff neck. A rash may be present on the arms, legs, neck, and trunk. The rash is typically erythematous, macular, and papular with or without morbilliform eruption.[155] Laboratory parameters may show normal or elevated WBC counts. Low serum sodium concentrations may be seen in patients with encephalitis. CSF usually shows pleocytosis, mostly with an elevation of lymphocytes, elevated protein levels, and normal glucose levels.[155] Magnetic resonance imaging (MRI) shows some enhancement of the leptomeninges or the periventricular areas in approximately one-third of patients, but no other abnormalities or evidence of acute disease are present on either CT or MRI examination.[155]

With disease progression, further muscle weakness and hyporeflexia may be observed. Patients may progress to a diffuse, flaccid paralysis similar to Guillain–Barré syndrome. Ataxia, extrapyramidal symptoms, cranial nerve abnormalities, myelitis, optic neuritis, and seizures may be seen.

Treatment

CASE 79-14, QUESTION 2: What treatment options are available to A.G.?

Currently, treatment of WNV infection is supportive. Patients with febrile infection usually have a self-limiting course. In severe cases, patients with muscle weakness and signs of encephalitis will require admission to an intensive care unit, and many will need mechanical ventilation. The available antiviral medications do not have any activity against WNV in vivo, although ribavirin inhibits replication in vitro.[155] Combination therapy of high-dose ribavirin and interferon-α-2b has been used in patients with severe disease with limited success. Although optimal doses have not been established, the doses needed to inhibit the virus were 2 to

3 million units of interferon and 2,400 mg of ribavirin daily.[156–158] Current clinical trials investigate the efficacy and safety of intravenous immunoglobulin and humanized monoclonal antibodies for treatment and vaccines for the prevention of WNV.

SEVERE ACUTE RESPIRATORY DISTRESS SYNDROME

Severe acute respiratory distress syndrome (SARS), a highly infectious disease, was first identified in China in early 2003. Since then, the viral syndrome has been reported in several countries in East Asia, North America (particularly Canada), South America, and Europe. During the 2003 outbreak, approximately 8,000 cases were reported, with a case fatality rate of about 10%.[159,160] No cases of SARS have been reported worldwide since 2004. Many of the pre-2004 cases reported in Asia and Canada have been traced to a single index case, with outbreaks clustered in apartments, hotels, health care facilities, or biomedical facilities. There is some evidence to suggest that increased age (older than 60 years) may be associated with an increased mortality risk.[161]

The disease is easily spread by airborne microdroplets. Geography and a history of recent travel to affected areas are believed to be important to an individual's likelihood of contracting the disease. In a sample of 100 suspected patients in the United States, 94% traveled within the 10 days before illness onset to an area listed in SARS case definitions.[162] SARS is believed to be transmitted mostly by close contact with an infected person (e.g., sharing eating utensils, <3-foot conversations).

A novel coronavirus, SARS coronavirus (SARS-CoV), was isolated from patients and identified as the causative agent of SARS. Inoculations of a Vero E6 cell line with throat swab specimens from patients with the diagnosis of SARS showed cytopathologic features.[163] Although the natural reservoir of SARS-CoV has not been identified, the virus has been detected in the Himalayan masked palm civet, the

Chinese ferret badger, and the raccoon dog.

Clinical Presentation

The case definition of SARS established by the CDC includes clinical, epidemiologic, laboratory, and exclusion criteria.[164] Symptoms of early disease include fever, chills, rigor, myalgia, headache, diarrhea, sore throat, or rhinorrhea. Mild-to-moderate illness includes temperature higher than 100.4°F and clinical findings of lower respiratory illness such as cough or shortness of breath. Severe illness is characterized by the previous criteria plus radiographic evidence of pneumonia or acute respiratory distress syndrome.

Probable or likely exposure to SARS-CoV is a critical component of the SARS case definition. Travel to a location with documented or suspected recent transmission of SARS-CoV and close contact with a person with mild-to-moderate or severe respiratory illness in the 10 days before the onset of symptoms are defined as possible exposures to SARS-CoV. Likely exposure is defined as close contact with a person with confirmed disease or symptoms of disease.[165]

For patients suspected of having SARS in the United States, laboratory diagnosis can be confirmed by an enzyme immunoassay detecting serum antibody to SARS-CoV, isolation of SARS-CoV from a clinical specimen, or detection of SARS-CoV RNA by a reverse transcriptase PCR. Both the enzyme immunoassay and the PCR are validated by the CDC.[163] Information regarding the most recent criteria for laboratory diagnosis can be found at the CDC website.

Although the majority of cases of infection are self-limited, initial symptoms may be followed by hypoxemia, which may progress to the need for intubation and mechanical ventilation. Typically, patients do not manifest neurologic or GI symptoms.

Treatment

Treatment for SARS during the 2002 through 2003 outbreak included broad-spectrum antibiotics, ribavirin, lopinavir/ritonavir, corticosteroids, interferon, and immunoglobulin.[165] Broad-spectrum antibiotics are recommended to cover other potential pathogens until infection attributable to SARS-CoV is confirmed. Ribavirin has been used in doses ranging from 400 mg IV every day to 2 g IV followed by 1 g IV every 6 hours with a duration of 4 to 14 days.[166] Interestingly, ribavirin does not inhibit SARS-CoV in vitro, and viral loads remained elevated after death despite therapy with ribavirin.[167,168] Furthermore, adverse drug reactions, including hemolytic anemia (61%), hypocalcemia (58%), and hypomagnesemia (46%), were common. Two of three in vitro studies of lopinavir and ritonavir showed activity against SARS-CoV. Lopinavir 400 mg PO BID with ritonavir 100 mg BID may be useful in the treatment of SARS, but data are limited.[165] Treatments with various corticosteroids, interferon, and immunoglobulin remain controversial. No treatment guidelines are available owing to the lack of prospective randomized controlled trials.

MIDDLE EAST RESPIRATORY SYNDROME

Middle East Respiratory Syndrome (MERS) was first reported in 2012 in Saudi Arabia. As of June 2015, a total of 1,130 cases have been reported, primarily in the Arabian Peninsula and most recently in the Republic of Korea.[169,170] To date, only two cases have been reported in the United States, both in health care workers who lived in Saudi Arabia and traveled to the United States. Both received supportive care at a hospital and were discharged.[171]

The causative organism of MERS is the Middle Eastern Respiratory Syndrome coronavirus (MERS-CoV). Symptoms of MERS include fever, cough, and shortness of breath. In some patients, gastrointestinal symptoms such as nausea, diarrhea, and vomiting have been reported. The infection progresses to complications including pneumonia and renal failure. Those at greatest risk for death have comorbid conditions, such as diabetes, cancer, heart disease, lung disease, or chronic kidney disease. Individuals with an underlying immunodeficiency may be at the greatest risk of death.[169]

MERS-CoV appears to be transmitted through close contact with an infected individual, likely through respiratory droplets. Most infections reported have occurred in hospitals or in individuals caring for or living with an infected individual.[169] Treatment of MERS is directed as supportive care for symptoms and complications.

ZIKA VIRUS

The Zika virus was first reported in 2007 in the Pacific Islands, with other rare outbreaks in Africa and Southeast Asia. In 2015, it was detected in Brazil and as of May 2016 reported areas of transmission include the Pacific Islands, the Caribbean, and South and Central America. Also as of May 2016, 503 cases related to travel have been reported in the United States.[172]

Zika is an RNA virus belonging to the Flaviviridae family. The most common symptoms of infection include fever, maculopapular rash, arthralgia, and conjunctivitis.[173] The infection is mild and self-limiting and generally resolves in 1 week. In some individuals, neurologic and autoimmune complications, such as Guillain–Barré syndrome, have been reported. Neonatal transmission in pregnant women infected with Zika virus has occurred resulting in microcephaly in the infant and loss of fetus in some instances.[173] Diagnosis is confirmed with RT-PCR, immunoglobulin M, and neutralizing antibody testing.

Zika is transmitted via a mosquito vector and can be transmitted sexually.[174] Women, particularly pregnant women, should use latex condoms or abstain from sexual activity with men who have traveled to an area with active Zika. The virus has been detected in the semen for up to 60 days after exposure.[175] Transmission from the female to the male has not been documented.[174] There is currently no vaccine or medication to prevent Zika virus infection. All travelers to or residents of areas with ongoing Zika virus transmission should follow steps to avoid mosquito bites because of the potential for exposure to Zika. Protective measures for prevention of infection with Zika include wearing long sleeve shirts and pants, remaining in air-conditioned areas with screens on windows, using insect repellent containing N,N-Diethyl-meta-toluamide (DEET), and sleeping in a mosquito net if traveling to an area with reported Zika.[176] Treatment of Zika virus is supportive.[177] Development of a vaccine against Zika virus is ongoing.

THE COMMON COLD

The most prevalent viral infection is the common cold. In the United States, approximately 62 million cases of the common cold occur annually.[178] An estimated 20 million and 22 million days of absence from work and school, respectively, occur. The frequency of the occurrence of a cold is greater in younger children and decreases with increasing age. Although the common cold is self-limiting, otitis media occurs in approximately 20% of children after infection.[179]

Many viruses have been isolated from patients with respiratory infections, but rhinovirus is the most common viral pathogen.[180] Rhinovirus accounts for approximately 34% of all respiratory illnesses. More than 100 different serotypes of rhinovirus exist, and the prevalence of each varies with time and geography. Other pathogens include coronavirus, parainfluenza, RSV, adenovirus, and enterovirus. Because of the number of pathogens known to cause the common cold, development of an effective vaccine remains difficult.

Treatment for the common cold is directed at pharmacologic treatment of symptoms. Nonsteroidal anti-inflammatory drugs, oral or intranasal decongestants, antihistamines, and antitussives may be used. However, these products provide minimal relief of symptoms and do not shorten the natural course of infection.[181–183] In pediatric patients younger than 4 years, the use of cough and cold medications is not recommended by the FDA because of the deaths associated with their use.[184–186] Currently, there are no specific antiviral treatments for the common cold.

Prevention

CASE 79-15

QUESTION 1: J.C. comes into the pharmacy asking for an herbal product that will help him prevent colds this upcoming cold season. He states that last year he had three colds and his neighbor had none. His neighbor had mentioned an herbal product he had been taking. J.C. cannot remember the name of the product but wonders whether there are any products that may be helpful.

ZINC

Zinc, a dietary supplement, has been studied in both the prevention and treatment of the common cold. The proposed mechanism of action is that the rhinovirus 3C protease is inhibited by zinc, and the inhibition of this enzyme prevents viral replication. In vitro, zinc has been shown to have antiviral activity. Several trials conducted in the past several decades have produced conflicting results on the benefits of zinc in decreasing symptom severity or duration. If started within 24 hours of symptom onset, zinc may shorten symptoms but not severity of the cold. Zinc lozenges, dosed at a minimum of 75 mg per day for the duration of cold symptoms, is recommended.[187] Patients who took zinc lozenges for the common cold complained of mouth irritation, unpleasant taste, feeling sick, and diarrhea. Daily administration of zinc is not currently recommended for prophylaxis of the common cold.

ECHINACEA

Echinacea is an herbal product extracted from the Echinacea plant, which belongs to the Compositae family. Echinacea is believed to stimulate the immune system, specifically phagocytosis. Some clinical trials using echinacea have shown positive results in decreasing the incidence of infection when compared with placebo, but the results remain inconclusive.[188] One study showed no benefit of echinacea versus placebo but did show an increased incidence of rash in the treatment group.[189] Because the current data are inconclusive and owing to the variability of echinacea concentrations in the available products, use of echinacea in the prevention and treatment of the common cold is not recommended.[190]

Viral Hepatitis

Jerika T. Lam and Curtis D. Holt

CORE PRINCIPLES		CHAPTER CASES
1	Hepatitis A virus (HAV) is a worldwide, acute self-limiting disease transmitted via the fecal–oral route. Hepatocyte injury is caused by a cytopathic and immunologic response, which can result in jaundice and increased liver function tests. Treatment measures are usually supportive and aimed toward prevention (pre-exposure and post-exposure) through vaccination.	**Case 80-1 (Questions 1–3), Case 80-2 (Question 1), Case 80-3 (Question 1)**
2	Hepatitis B virus (HBV) is a bloodborne pathogen that is transmitted through percutaneous or perinatal exposure, blood products, or sexual contact. HBV has an acute phase with resolution and a chronic phase. Over the course of decades, the chronic phase can lead to hepatic cirrhosis and death. Patients with chronic infection require treatment with peginterferon, nucleoside and nucleotide reverse transcriptase (RT) inhibitors. Several effective prophylactic strategies (immunizations and nucleoside or nucleotide RT inhibitors) are used to prevent HBV infection.	**Case 80-4 (Questions 1–4), Case 80-5 (Questions 1, 2), Case 80-6 (Questions 1–3), Case 80-7 (Question 1), Case 80-8 (Question 1), Case 80-9 (Question 1), Case 80-10 (Questions 1, 2), Case 80-11 (Question 1), Case 80-12 (Questions 1–14)**
3	Hepatitis C virus (HCV) is a bloodborne pathogen that is transmitted primarily through percutaneous exposure, blood products, or sexual contact. HCV has an acute and a chronic phase. The chronic phase can lead to cirrhosis, decompensated liver disease, hepatocellular carcinoma, and death. Acute clinical manifestations are similar to those for HAV and HBV. Treatment of chronic HCV infection (genotypes 1 to 6) is with direct-acting antivirals (DAAs).	**Case 80-13 (Question 1), Case 80-14 (Questions 1–3), Case 80-15 (Questions 1–3)**
4	Hepatitis Dvirus (HDV) is a small RNA virus that requires coinfection with HBV for replication. HDV transmission is most likely associated with percutaneous exposure. HDV, in combination with HBV, leads to a much higher risk of acute liver failure. Prevention strategies rely on successful immunization of HBV.	**No cases**
5	Hepatitis E virus is similar to HAV and is transmitted via the fecal–oral route, especially through contaminated water, which is found more common in developing countries. Recovery from acute illness usually occurs.	**No cases**

There are five distinctly separate hepatitis viruses that cause liver disease. A sixth virus also has been identified, but has yet to be implicated in liver disease. Four of these viruses are RNA viruses, and one is a DNA virus.[1] The individual virus types can be distinguished by serologic assays and, in some instances, by genotyping. Although progress in the area of disease prevention has improved, advances in treatment of certain viral infections have been limited because of the large amount of viruses produced and their rapid mutation. For instance, the hepatitis C virus (HCV) replicates approximately 1 trillion virus particles (virions) daily, compared with 100 billion HBV virions daily and 10 billion HIV virions daily.[1,2] This chapter reviews the virology, epidemiology, pathogenesis, natural history, diagnosis, clinical manifestations, prevention, and treatment strategies for viral hepatitis A through E.

CAUSATIVE AGENTS AND CHARACTERISTICS

Viral hepatitis is a major cause of morbidity and mortality in the United States.[1–3] At least five distinct pathogens are responsible for viral hepatitis. These hepatotrophic viruses are identified by the letters A through E as follows: (a) type A hepatitis caused by hepatitis A virus (HAV), (b) type B hepatitis caused by hepatitis B virus (HBV), (c) type C hepatitis caused by HCV, (d) type D or delta hepatitis caused by the HBV-associated hepatitis D virus (HDV), and (e) type E hepatitis caused by the hepatitis E virus (HEV). Hepatitis A through E viruses differ in their immunologic characteristics and epidemiologic patterns (Table 80-1).[4,5] Fecal–oral transmission is the primary mode of infection for HAV and HEV, whereas parenteral and sexual transmission is characteristic of HBV, HCV, and HDV infections.[1–3] Several other viruses primarily affect nonhepatic organ systems and may secondarily induce a hepatitis-like syndrome. These include the Epstein–Barr virus (infectious mononucleosis), cytomegalovirus, herpes simplex viruses, varicella-zoster virus, and rubella, rubeola, and mumps viruses.

Table 80-1

Characteristics of Hepatitis Viruses[4,5]

Virus	Nucleic Acid	Routes of Transmission	Risk of Chronic Illness	Mortality
HAV	Nonenveloped SS RNA	Fecal–oral	None	Low
HBV	Enveloped DS DNA	Parenteral (sex, perinatal)	High	Moderate–High
HCV	Enveloped SS RNA	Parenteral (sex, perinatal)	High	Moderate–High

HDV	Enveloped SS RNA	Parenteral (sex, perinatal)	High	High
HEV	Nonenveloped SS RNA	Fecal–oral	None	Low–Moderate

HAV, hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HDV, hepatitis D virus; HEV, hepatitis E virus; SS, single-stranded; RNA, ribonucleic acid; DNA, deoxyribonucleic acid.

Definitions of Acute and Chronic Hepatitis

Viral hepatitis can present as either an acute or chronic illness. Acute hepatitis is defined as an illness with a discrete date of onset with jaundice or increased serum aminotransferase concentrations greater than 10 times the upper limit of normal[1–3,5] and does not exceed 6 months. Chronic hepatitis is a prolonged inflammatory condition of the liver that involves ongoing hepatocellular necrosis for ≥6 months beyond the onset of acute illness.[4,5] The most common causes of chronic viral hepatitis are HBV and HCV.[3] Drug-induced and autoimmune chronic hepatitis occur less frequently; metabolic disorders and HDV chronic hepatitis are relatively rare.[6,7] HAV and HEV are self-limiting infections that rarely progress to chronic hepatitis.

Serologic Evaluation in Presumed Chronic Hepatitis

Serologies are useful in diagnosing viral hepatitis. Antibodies against hepatitis A virus (anti-HAV), hepatitis B surface antigen (HBsAg), and hepatitis C virus (anti-HCV) are useful diagnostic markers. A diagnosis of acute HAV infection includes the presence of immunoglobulin M (IgM) anti-HAV. If HBsAg is present, further testing for hepatitis B envelope antigen (HBeAg) and HBV DNA confirms the presence of active viral replication and viral load, respectively. Testing for hepatitis D antibody (anti-HDV) should also be performed in patients with HBV infection to evaluate the possibility of coinfection. If serology is negative, rare but treatable causes of chronic active hepatitis should be further ruled out. These include alcoholic liver disease, disease, alpha-1-antitrypsin deficiency, and drug-induced chronic active hepatitis. Drugs associated with reversible chronic active hepatitis syndrome include methyldopa,[8] nitrofurantoin,[9] isoniazid,[10] and, rarely, sulfonamides[11] and propylthiouracil.[12]

HEPATITIS A VIRUS

Virology and Epidemiology

Hepatitis A virus is an icosahedral, nonenveloped virus measuring 28 nm diameter. It is a single-stranded, positive-sense, linear RNA enterovirus of the Picornaviridae family (see Table 80-1).[2,4,5]

HAV has a worldwide distribution.[13,14] The prevalence of infection is related to the quality of the water supply, level of sanitation, and age.[14,15] Incidence data are unreliable because the disease is frequently mild and often unrecognized, resulting in under-reporting. The primary mode of transmission is from person to person via the fecal–oral route.[15,16] The virus is sturdy and resists degradation by drying, environmental conditions (temperatures as high as 56°C and as low as −20°C), gastric acid (pH 3.0), and digestive enzymes in the upper gastrointestinal (GI) tract. Therefore, HAV is easily spread within a population. Fecally contaminated water or food is a significant mode of transmission.[16,17] Children are considered a relatively common reservoir, but rarely exhibit clinical symptoms.[17,18]

In 2014, the overall incidence rate of HAV infection was 0.4 cases per 100,000 population in the United States.[19] HAV infection could occur from common-source outbreaks of fecally contaminated food or water, as well as uncooked HAV-contaminated foods. In developed countries with well-maintained sanitation and water supplies, waterborne outbreaks of HAV are uncommon.[19] Originally, HAV vaccination was recommended for persons at high risk of infection and children living in communities at high risk. However, due to the significant number of cases of HAV disease still occurring in the United States, HAV vaccination recommendations have expanded. In 2006, the Advisory Committee on Immunization Practices (ACIP) recommended routine vaccination for all children aged 12 to 23 months in the United States.[20]

Exceedingly rare causes of HAV include transfusion of blood or blood products collected from donors during the viremic phase of their infection and from contact with experimentally infected nonhuman primates.[16,21] Percutaneous transmission is rare because no asymptomatic carrier state for HAV exists and the incubation period is brief.[16] Occupations at risk for HAV infection include sewage workers, hospital cleaning personnel, day-care staff, and pediatric nurses.[18,19] HAV is the most common preventable (e.g., vaccination) infection in travelers visiting locations with poor hygienic conditions.[22]

Pathogenesis

Although the exact mechanism of injury is unknown,[17,23,24] viral replication occurs within the liver, or hepatocytes. Subsequent hepatocyte death results in viral elimination and eventual resolution of the clinical illness.[18]

Natural History

After exposure to HAV, usually via ingestion of HAV from material contaminated with feces, the virus resides and replicates in the hepatocytes within hours or days after infection. Following the translational and replication processes, HAV is released into the bile canaliculi and is transported to the intestine, where it is excreted in the feces at concentrations ranging up to 10^9 infectious virions per gram of feces.[17] This occurs during the subclinical stage (incubation period) or anicteric prodromal period (14–21 days) of the infection before alanine aminotransferase (ALT) levels become elevated and clinical symptoms or jaundice occurs.[18] The contagiousness of the infection is highest during this period and is significantly reduced following the onset of symptoms or jaundice. HAV infection could occur in two clinical courses varying from subclinical hepatitis (asymptomatic), usually observed in children, to anicteric hepatitis (symptoms without jaundice) or icteric hepatitis that occurs in adults and could result in fulminant hepatitis and death, especially among adults older than 50 years.[18] Chronic HAV infection usually does not manifest because of the robust humoral and cellular immune responses, particularly natural killer cells, $CD4^+$ and $CD8^+$ cytotoxic T cells.[18] Most important, humoral immunity plays a pivotal role in viral clearance leading to viremia declines after the presence of neutralizing antibodies.[25] Typically, the course of HAV includes an incubation phase, an acute hepatitis phase, and a convalescent phase. Complete clinical recovery is usually seen in all patients within 6 months after HAV infection.

Clinical Manifestations

CASE 80-1

QUESTION 1: E.T., a 34-year-old medical sales representative, presents to the emergency department (ED) with acute onset of jaundice and "dark urine." He was in good health until 2 weeks ago, when he noted feeling fatigued and weak, which he attributed to his demanding work schedule. He also recalled having a mild headache, loss of appetite, muscle pain, diarrhea, and low-grade fevers from 99°F to 101°F. He attributed these symptoms to the flu and took acetaminophen with plenty of fluids. His symptoms persisted until yesterday, when they seemed to resolve unexplainably. He then noted his urine was cola-colored. This morning, he noted jaundice of his eyes and skin and sought medical attention.

E.T.'s medical history includes a recent respiratory tract infection, treated successfully with levofloxacin. His social history is significant for frequenting the local oyster bar, where he regularly ingests raw oysters. He denies smoking and recent travel outside the United States, but admits to occasional alcohol consumption. E.T. has no history of sexual exposure, needle use, or transfusions. His current medications include oral (PO) diazepam 5 mg at bedtime (HS) as needed (PRN) for "muscle spasms," but he has not taken diazepam for "several months." He also has a seizure disorder sustained after a motorcycle accident 2 years before admission, for which he takes phenytoin 400 mg PO every HS.

Physical examination is significant for a well-developed, well-nourished man in no acute distress. He is alert and oriented, with a temperature of 99°F. His sclerae and skin are icteric, and his abdomen is positive for a tender, enlarged liver and right upper quadrant pain. Laboratory tests reveal the following values:

Hemoglobin (Hgb): 16 g/dL
Hematocrit (Hct): 44%

White blood cell (WBC) count: 5,500 cells/μL
Aspartate transaminase (AST): 120 units/L
Alanine aminotransferase (ALT): 240 units/L
Alkaline phosphatase: 86 units/L
Total bilirubin: 3.2 mg/dL
Direct bilirubin: 1.5 mg/dL
Phenytoin concentration: 12 mg/L (normal: 10–20 mg/L)

The albumin, prothrombin time (PT), blood glucose, and electrolytes all are within normal limits. E.T. is negative for anti-HCV, HBeAg, HBsAg, and hepatitis B core antibody (anti-HBc), but is positive for IgM anti-HAV. What clinical features and serologic markers are consistent with viral hepatitis in E.T.?

The incubation period for HAV is 15 to 50 days (average 28 days) after inoculation. The host is usually asymptomatic during this stage of the infection; thus, E.T. is beyond the inoculation phase of the disease. Because HAV titers are highest in the acute-phase fecal samples, the period of infectivity is 14 and 21 days, before the onset of jaundice, to 7 or 8 days after jaundice. Therefore, E.T. should be considered infectious at this time. In HAV infections, acute-phase serum and saliva are less infectious than fecal samples, whereas urine and semen samples are not infectious. Family members and persons recently in immediate contact with E.T. should be notified.[26]

The symptoms of acute viral hepatitis caused by HAV, HBV, HCV, HDV, and HEV are similar. The onset of symptoms in HAV infection, however, is less insidious than those seen with HBV and HCV infection.[5] Generally, symptoms of HAV infection present a week or more before the onset of jaundice. The likelihood of having symptoms is related to age. In children younger than 6 years of age, 70% of infections are asymptomatic, whereas older children and adults have symptomatic disease with jaundice occurring in more than 70% of cases.[18] E.T. has signs and symptoms of acute HAV infection, including the nonspecific prodromal symptoms of fatigue, weakness, anorexia, nausea, and vomiting. Abdominal pain and hepatomegaly are common. Less common symptoms include fever, headache, arthralgias, myalgias, and diarrhea. Within 1 to 2 weeks of the onset of prodromal symptoms, patients may enter an icteric phase with symptoms, including clay-colored stools, dark urine, scleral icterus, and jaundice. The dark urine is caused by bilirubin, generally occurring shortly before the onset of jaundice. E.T. should be questioned about the presence of pale stools (light gray or yellow), which usually is observed during the icteric phase. His scleral icterus is strongly suggestive of viral hepatitis. Icteric infections usually occur in adults and are 3.5 times more common than the nonicteric presentation that is seen in children.[16,26]

The results of E.T.'s liver function tests (e.g., elevations in AST, ALT, and total bilirubin) also are consistent with viral hepatitis. Serum transaminase concentrations increase during the prodromal phase (usually ALT > AST) of HAV infection, peaking before the onset of jaundice. These concentrations are often greater than 500 units/L and decline at an initial rate of 75%/week, followed by a slower rate of decline thereafter. Serum bilirubin peaks after aminotransferase activity and rarely exceeds

10 mg/dL. Total bilirubin levels decline more slowly than aminotransferases and generally normalize within 3 months. Right upper quadrant tenderness, mild liver enlargement, and splenomegaly may also be present in patients with acute HAV infection.[5,26]

Extrahepatic Manifestations

CASE 80-1, QUESTION 2: Are there any additional complications that E.T. could experience from his acute HAV infection?

With the appearance of jaundice, prodromal pruritus and extrahepatic manifestations can occur, usually in patients with a more protracted illness. E.T. should be monitored for additional manifestations of HAV infection, including immune complex-associated rash, leukocytoclastic vasculitis, glomerulonephritis, cryoglobulinemia (less likely than with HCV), and arthritis.[26]

Diagnosis and Serology

Diagnostic methods for detecting HAV antigen and anti-HAV are listed in Figure 80-1. Detection of IgM antibodies to HAV in a patient who presents with clinical characteristics of hepatitis, or in an asymptomatic patient with elevated transaminases, is consistent with acute HAV infection. HAV IgG appears after IgM and is indicative of previous exposure and immunity to HAV, whereas a rising IgG is consistent with recent exposure.[5,26] Anti-HAV IgM is commonly present throughout the disease course (16–40 weeks), usually peaking early and declining to undetectable levels 3 to 4 months after the initial infection.[26] One-quarter of patients infected with HAV have IgM present for up to 6 months and occasionally longer. HAV IgG appears early in the convalescent phase and is detectable for decades after the acute infection resolves, with a slowly declining titer.[16,26] Both enzyme-linked immunosorbent assay (ELISA) and radioimmunoassay methods of antibody detection are sensitive, specific, and reliable to diagnose acute HAV infection. E.T. has a positive IgM anti-HAV, consistent with acute HAV infection. He has a negative IgM anti-HBc test, ruling out acute HBV infection.[16,26]

Treatment

GENERAL MEASURES

HAV infection is usually a self-limiting disease and rarely leads to serious complications including fulminant liver failure and death.[27] Management involves supportive care and medical treatment of serious complications. Intravenous (IV) fluid and electrolyte replacement, nutritional support, and the use of antiemetics may be necessary for some patients. Antipyretics (acetaminophen) should not be used because the risk of fulminant hepatic failure (FHF) could increase. Considering that hemolysis or acute kidney injury is possible, a regular assessment of renal function with a complete blood count (CBC) should be performed. Patients should abstain from alcohol during the acute phase of the disease. After resolution of symptoms and serum biochemical abnormalities, moderate alcohol intake is no longer contraindicated. In general, prognosis after HAV infection is very good. Long-term immunity accompanies HAV infection, and recurrence or chronic hepatitis usually does not occur.

Adjustment of Medication Doses

CASE 80-1, QUESTION 3: Should E.T.'s medications be adjusted during the acute phase of HAV infection?

Dosage adjustments for hepatically eliminated drugs in the setting of liver disease are difficult to predict. This is because hepatic metabolism is complex, involving numerous oxidative and conjugative pathways that are variably affected in hepatic disease. In renal disease, creatinine serves as an endogenous marker to predict the clearance of renally eliminated drugs. In hepatic disease, however, no reliable endogenous markers exist to predict drug hepatic clearance. Laboratory tests that approximate the synthetic function of the liver (e.g., albumin, PT) and biliary clearance (bilirubin) are used to estimate the degree of hepatic impairment, but these tests are not dependable in predicting alterations in pharmacokinetic parameters for hepatically metabolized drugs. Unnecessary and potentially hepatotoxic medications should be avoided during the acute phase of the illness. When drug therapy is indicated with agents that undergo hepatic elimination, it is prudent to use the lowest doses possible to achieve the desired therapeutic effect.

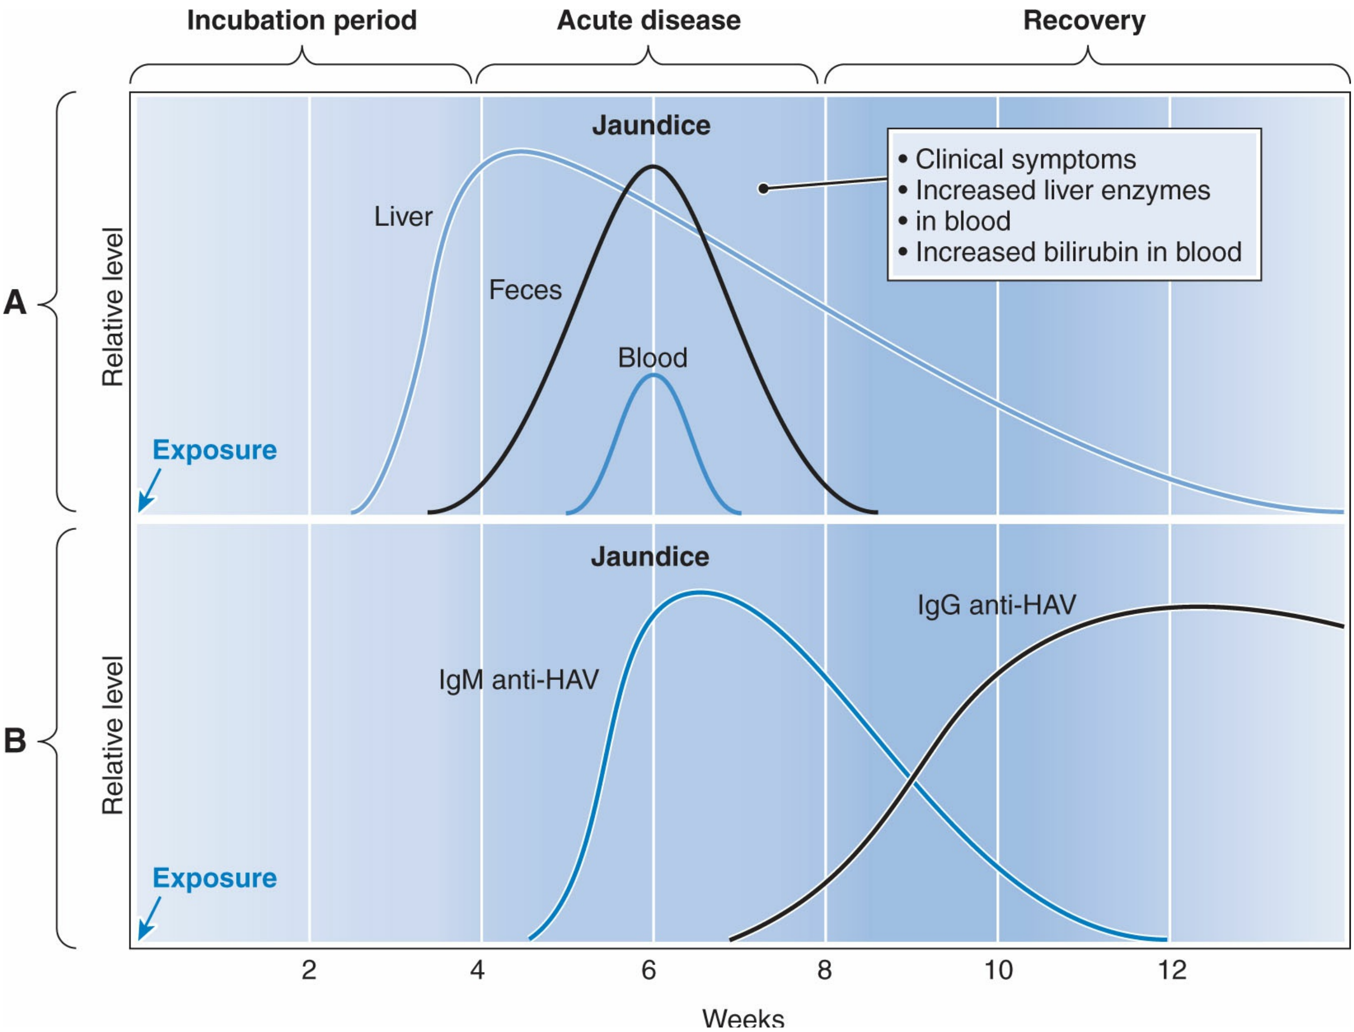

Figure 80-1 Typical course of hepatitis A. anti-HAV, antibody to HAV; HAV, hepatitis A virus. **A:** Presence of hepatitis A virus in liver, feces, and blood. **B:** Markers of hepatitis A virus in blood. (Adapted from McConnell TH, The Nature of Disease Pathology for the Health Professions. Philadelphia, PA: Lippincott Williams & Wilkins, 2007, with permission.)

E.T. should be advised to discontinue diazepam because this medication undergoes extensive hepatic biotransformation and limited data suggest this agent accumulates in the setting of acute viral hepatitis.[28] If E.T. should require drug therapy for muscle spasms, he should either decrease the diazepam dose or consider using an alternative agent (e.g., lorazepam) that does not accumulate in acute viral hepatitis.[29] Patients with acute viral hepatitis do not require phenytoin dosage adjustments.[30] Because E.T.'s plasma phenytoin concentration is within the desired therapeutic range, no dosage adjustment is needed.

Prevention of Hepatitis A

Prevention of hepatitis A infection can be achieved through immunoprophylactic measures. Immunoprophylaxis may be passive, active, or a combination of both. In passive immunization, temporary protective antibody in the form of immunoglobulin is administered. In active immunization, a vaccine is administered to induce the formation of protective antibody.[20,31] Prophylaxis can be administered before (pre-exposure prophylaxis) or after exposure (post-exposure prophylaxis).

Pre-Exposure Prophylaxis

CASE 80-2

QUESTION 1: M.D., a 22-year-old student, is preparing for a 2-week vacation to Thailand. He plans to travel 3 months from now and wonders whether he should receive prophylaxis for HAV.

Immunoglobulin

Before hepatitis A vaccine was available, the only therapy for pre-exposure prophylaxis of hepatitis A infection was immunoglobulin. Although passive immunization with immunoglobulin alone is highly effective in preventing HAV infection,[20] the duration of protection is short. When used for pre-exposure prophylaxis (e.g., in travelers who are allergic to a vaccine component or decide against vaccination), a dose of 0.02 mL/kg of immunoglobulin administered intramuscularly (IM) confers protection for less than 3 months, and an IM dose of 0.06 mL/kg confers protection for 5 months or longer.[19,20,26]

Table 80-2

Recommended Doses of Hepatitis A Vaccines[27,31,32]

Age at Vaccination	Dose (Volume)[a]	Schedule (Months)[b]
Havrix		
Children 12 months–18 years	720 ELISA units (0.5 mL)	0, 6–12
Adults >19 years	1,440 ELISA units (1.0 mL)	0, 6–12
Vaqta		
Children 12 months–18 years	25 units (0.5 mL)	0, 6–18
Adults >19 years	50 units (1.0 mL)	0, 6

[a] Enzyme-linked immunosorbent assay (ELISA) units.

[b] Zero months represent timing of the initial dose; subsequent numbers represent months after the initial dose.

Vaccine

Active immunization with hepatitis A vaccine has largely supplanted the use of immunoglobulin for pre-exposure prophylaxis of infection caused by HAV. Two types of the inactivated, monovalent hepatitis A vaccines are available in the United States and globally: Havrix and Vaqta. Both vaccines are formalin-inactivated preparations of attenuated HAV strains.[32] The manufacturers use differing units to express antigen content of their respective vaccines. Havrix dosages are expressed in ELISA units, and Vaqta dosages are expressed as units of hepatitis A antigen. These vaccines are developed to provide long-term immunity. They are free of thimerosal and mercury as preservatives and are safe and effective for children and adults.[33]

Dosing Regimen

Havrix is available in two formulations that differ according to age: for persons 12 months to 18 years of age, 720 ELISA units (0.5 mL)/dose in a two-dose schedule; and for persons 19 years and older, 1,440 ELISA units (1.0 mL)/dose in a two-dose schedule (Table 80-2).[27,31,32] Havrix is injected IM into the deltoid muscle with a booster dose administered 6 to 12 months later. The pediatric Havrix formulation (three-dose schedule) is no longer available. Vaqta is available in two formulations that differ according to the person's age: for persons 12 months to 18 years of age, 25 units (0.5 mL) in a two-dose schedule; and for persons 19 years and older, 50 units (1.0 mL) per dose in a two-dose schedule (Table 80-2).[27,31,32] Likewise, this vaccine is injected IM into the deltoid muscle with a booster dose administered 6 to 18 months later.[20,31,32]

Combination Vaccine

The US Food and Drug Administration (FDA) has also licensed a combined HAV and HBV vaccine (Twinrix) for use in persons aged 18 years and older. Twinrix is composed of the same antigenic components used in Havrix and Engerix-B. Each dose of Twinrix contains at least 720 ELISA units of inactivated HAV and 20 mcg of recombinant HBsAg.[34,35] Twinrix does not contain thimerosal and mercury as preservatives and is safe and effective for children and adults.[33]

Primary immunization consists of three doses, given on a 0-, 1-, and 6-month schedule, the same that is used for single-antigen hepatitis B vaccine.[34,35] Any person 18 years of age and older having an indication for both hepatitis A and hepatitis B vaccine can receive Twinrix, including persons with chronic liver disease, injection drug users, men who have sex with men (MSM), persons who have occupational risk for infection (e.g., who work with HAV-infected primates), and persons with clotting factor disorders who receive therapeutic blood products.[34,35] For international travel, hepatitis A vaccine is recommended; hepatitis B vaccine is recommended for travelers to areas of high or intermediate hepatitis B endemicity who plan to stay for longer than 6 months and have frequent close contact with the local population.[36]

Efficacy, Safety, and Duration of Response

The efficacy of the hepatitis A vaccine is well established, with protective efficacy of 94% to 100%.[34] The vaccine is well tolerated, with soreness at the injection site, headache, myalgias, and malaise as the most commonly reported adverse effects.

The duration of protection from the vaccines has not been studied extensively. However, protective levels of antibody to HAV could be present for at least 14 to 20 years in children and at least 25 years in adults.[32,34] The ACIP has no recommendations regarding the need for booster doses at this time. The safety of HAV vaccine during pregnancy has not been established. However, because the vaccine is produced from inactivated HAV, the

---

theoretic risk to the developing fetus is low. The benefits versus risks associated with vaccination for HAV in women who might be at high risk for exposure to the infection should be discussed with her primary care physician and obstetrician.[19]

Indications

The ACIP recommends hepatitis A vaccination for several high-risk groups, including travelers to countries with high endemicity of infection (South and Central America, Africa, South and Southeast Asia, Caribbean, and the Middle East),[37–39] travelers to countries with intermediate endemicity of infection (Eastern and Southern Europe and the former Soviet Union), children living in communities with high rates of hepatitis A infection and periodic hepatitis A outbreaks (Alaskan Native villages, American Indian reservations), MSM, injection drug users, researchers or persons who have occupational risk for hepatitis A (healthcare workers), persons with clotting factor disorders, and persons with chronic liver disease who are at increased risk for fulminant hepatitis A.[20,27,31,32] Thus, M.D. should receive either Havrix 1,440 ELISA units or Vaqta 50 units. This initial injection will provide adequate protection from HAV infection during his travel, and he can receive the booster injection on his return, at least 6 months after the first injection. If M.D. decides to travel within the next 2 weeks, he should receive both vaccination and immunoglobulin before departure.[36]

POSTEXPOSURE PROPHYLAXIS

CASE 80-3

QUESTION 1: L.W., a 26-year-old man, recently was diagnosed with HAV infection. He attends college and works part-time as a retail clerk. He lives with his healthy, 25-year-old wife and 10-month-old infant daughter. Which of L.W.'s contacts require postexposure prophylaxis for HAV?

Although immune globulin has been recommended in the past for unvaccinated people recently exposed to HAV, hepatitis A vaccines (Havrix and Vaqta) are effective in preventing secondary HAV infection in healthy people. Twinrix is not recommended for postexposure prophylaxis.[19] A vaccine can be administered in healthy people age 12 months to 40 years within 2 weeks after exposure to HAV.[31,36] However, at this time, individuals outside of this age range or with significant comorbid conditions should receive immune globulin instead of the vaccine.

Therefore, L.W.'s wife should receive prophylactic administration of HAV vaccine and his 10-month-old infected daughter should receive immune globulin at a dose of 0.02 mL/kg, administered IM as soon as possible but no later than 2 weeks after exposure. Contacts who have received a dose of hepatitis A vaccine at least 1 month before exposure do not need immune globulin, because protective antibody titers are achieved in greater than 95% of patients 1 month after vaccination.[20] Prophylaxis is not recommended for casual contacts at work or school.

Administration of immune globulin within 2 weeks after exposure to HAV is 80% to 90% effective in preventing acute HAV infection.[20,26] In most cases, when given early, immune globulin prevents both clinical and subclinical HAV illness. Protection after immune globulin administration is immediate and complete, but short-lived. Other situations in which immune globulin administration may be indicated include hepatitis A infection in day-care centers and in settings with infected persons who prepare and serve food. Immune globulin is recommended for all staff and children in day-care settings when a case of HAV infection is diagnosed among employees or attendees.[15,19,20] When a food handler is diagnosed with hepatitis A, immune globulin is recommended for other food handlers at the same location. Given the improbability of disease transmission to persons consuming food prepared or served by workers infected with hepatitis A, the routine administration of immune globulin in this setting is not recommended.[15,20]

When immune globulin is required for infants or pregnant women, preparations free of thimerosal should be used.[15] Although immune globulin does not impede the immune response to inactivated vaccines, oral poliovirus vaccine, or yellow fever vaccine, it may interfere with the response to live attenuated vaccines such as measles, mumps, rubella (MMR) vaccine and varicella vaccine. Therefore, MMR and varicella vaccines should be delayed for at least 3 months after administration of immune globulin for HAV prophylaxis. Immune globulin should not be given within 2 weeks after the administration of MMR or varicella vaccine. Finally, if immune globulin is administered within 2 weeks of MMR, the person requires revaccination, but not sooner than 3 months after the immune globulin administration for MMR.[15,19,20] Serologic tests for varicella vaccination should be performed 3 months after immune globulin administration to determine whether revaccination is required.

HEPATITIS B VIRUS

Virology

Hepatitis B virus is an icosahedral, enveloped, and encapsulated virus measuring 42 nm diameter and belongs to the Hepadnaviridae family of viruses.[40–43] The viral genome is a partially double-stranded, circular DNA linked to a DNA polymerase. Unlike HAV, HBV is antigenically complex and results in an acute illness with or without a chronic disease state. HBV infection can produce either asymptomatic or symptomatic infection. The average incubation period is 90 days (range: 60–150 days) from exposure to the onset of jaundice and 60 days (range: 40–90 days) from exposure to onset of abnormal serum ALT levels.[42–43]

The life cycle of HBV is described in Figure 80-2. Elucidation of the HBV life cycle has resulted in opportunities for drug development. Of special importance, the viral DNA polymerase functions as both a reverse transcriptase (RT) for synthesis of the negative DNA strand from genomic RNA and as an endogenous DNA polymerase. Because the HBV polymerase is remotely related to the RT enzymes of retroviruses (e.g., HIV), some inhibitors of HIV polymerase or RT also have activity against the HBV polymerase. Thus, several RT inhibitors have been evaluated for treating and preventing HBV; however, rapid emergence of resistance occurs with many of these agents.

Epidemiology

Globally, approximately 2 billion persons are infected with HBV, and between 350 and 400 million persons are living with chronic HBV infection.[44,45] HBV disease causes approximately 1 million deaths from cirrhosis, liver failure, and hepatocellular carcinoma (HCC).[46–48] In 2002, more than 600,000 persons died of HBV-associated acute and chronic liver disease.[44,45] In the United States, HBV infection affects an estimated 2.2 million persons and accounts for an estimated 5,500 deaths annually.[47,48]

Acute HBV infection is usually asymptomatic in infants and children aged less than 5 years compared to 30% to 50% of children older than 5 years and adults who could develop clinical signs and symptoms.[49] Clinical signs and symptoms can include anorexia, nausea, vomiting, abdominal pain, malaise and jaundice. Extrahepatic manifestations of HBV disease may include skin rashes, arthralgias, and arthritis.[50] Approximately 95% of primary infections in immunocompetent adults are self-limiting, with elimination of the virus from blood and subsequent lasting immunity to reinfection. Progression from acute to chronic HBV infection is influenced by the person’s age at acquisition of the virus. Chronic HBV infection occurs in approximately 30% of infected children younger than 5 years old, and less than 5% of infected persons older than 5 years.[49] Persons who are HBV infected and are at risk for developing chronic HBV disease include immunosuppressed persons (e.g., persons with diabetes, HIV, or on hemodialysis).[50]

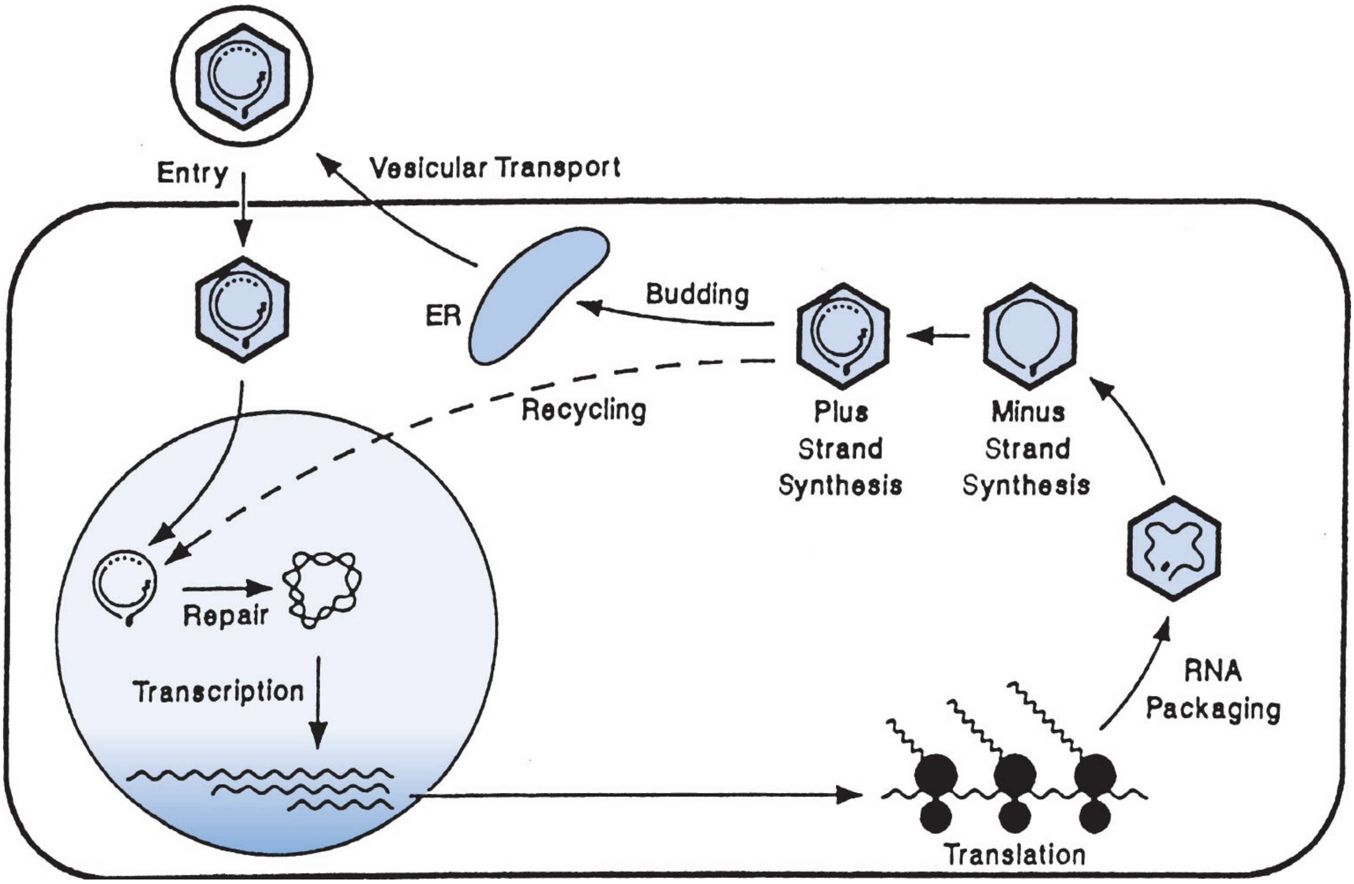

Figure 80-2 Life cycle of hepatitis B virus. ER, endoplasmic reticulum. (Reprinted from Ganem D. Hepadnaviridae: the viruses and their replication. In: Fields BN, ed. Fundamental Virology. 3rd ed. Philadelphia, PA: Lippincott-Raven; 1996:1199, with permission.)

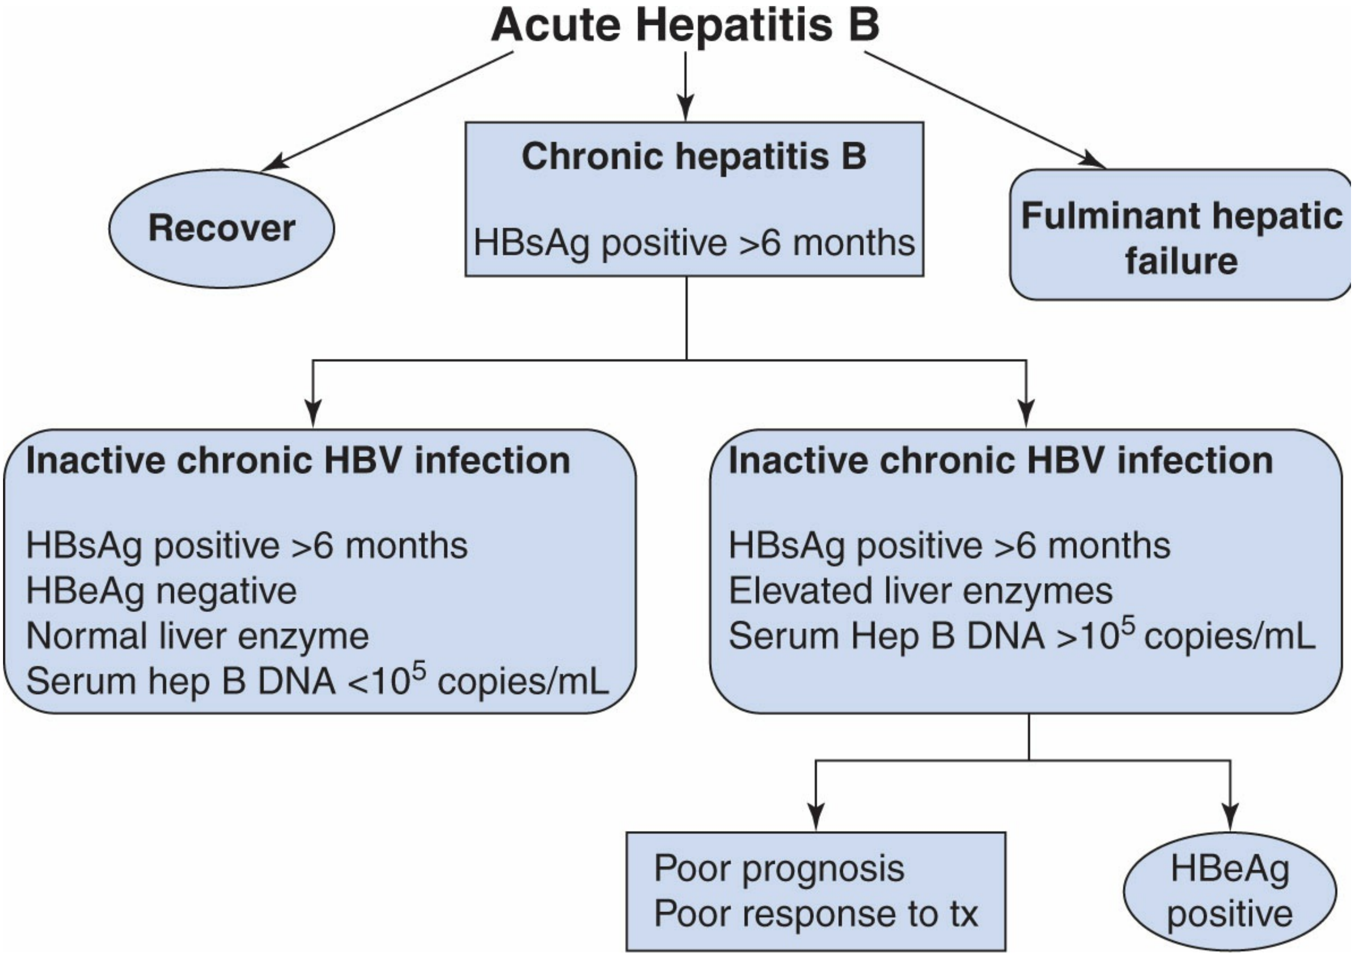
With respect to HBV infection in certain parts of the world, HBV infection is acquired perinatally in Asia. The cellular immune responses to hepatocyte-membrane HBV proteins that are associated with acute hepatitis do not occur, and chronic, lifelong infection is established in more than 90% of persons infected in Asia.[51] On the other hand, most acute HBV infections that occur in the West are reported during adolescence and early adulthood because of behaviors and environments that favor the transmission of bloodborne infections, such as sexual activity, injection drug use, and occupational exposure. There are no specific treatment for acute HBV, and supportive care is the mainstay of therapy.[51,52]

Similar to HAV infection, chronic HBV infection is defined as persons positive for HBsAg for >6 months (Fig. 80-3). The incidence of acute HBV infection has declined in the United States by approximately 82% since 1991.[45,52–54] This reduction of infection occurs in all age, racial, ethnic, and high-risk groups, particularly among children and healthcare workers—the groups with the highest rate of vaccination. Less high-risk behaviors also have led to decreased transmission of infection. High-risk groups in the United States for acquiring HBV infection include certain ethnic groups (e.g., Alaskan Eskimos, Asian Pacific Islanders), first-generation immigrants from regions of high endemicity (e.g., India, Central and Southeast Asia), injection drug users, MSM, African-Americans, and males (more than females).[52–54] The most prominent risk factors associated with acute HBV infection include heterosexual contact (42%), MSM (15%), and injection drug use (21%).[52–54] HBV vaccination opportunities include clinics for sexually transmitted disease (STD), correctional facilities, and holding centers for incarceration.



Acute Hepatitis B
Recover
Chronic hepatitis B
HBsAg positive >6 months
Fulminant hepatic failure
Inactive chronic HBV infection
HBsAg positive >6 months
HBeAg negative
Normal liver enzyme
Serum hep B DNA <10^5 copies/mL
Inactive chronic HBV infection
HBsAg positive >6 months
Elevated liver enzymes
Serum Hep B DNA >10^5 copies/mL
Poor prognosis
Poor response to tx
HBeAg positive

Transmission

The transmission of HBV is from exposure to blood, semen, and other body fluids infected with HBV. Furthermore, HBV transmission could occur among unvaccinated adults with risky behaviors, including sexual contact, and percutaneous or perinatal exposure to infectious blood or body fluids. HBV is highly concentrated in serum with lower concentrations in semen and saliva.[49] The modes of HBV transmission include sexual, blood transfusion, perinatal transmission, and injection drug use are summarized in the following sections.

SEXUAL TRANSMISSION

Sexual activity, especially unprotected sex and having multiple sex partners, is the most significant mode of HBV transmission worldwide, including North America, where the prevalence of infection is low.[52–54] Heterosexual intercourse accounts for the majority of US infections (26%). In heterosexual persons, factors associated with an enhanced risk of HBV infection include duration of sexual activity, number of sexual partners, and history of STD. Sexual partners of injection drug users, sex workers, and clients of sex workers are at a very high risk for infection. Sexual partners of infected individuals are at high risk for infection, even in the absence of high-risk behavior. Because most patients with chronic HBV infection are unaware of their infection and are "silent carriers," sexual transmission is a significant mode of transmission. Many of the HBV infections could have been prevented through universal vaccination. The use of condoms appears to reduce the risk of sexual transmission.[52–54]

From 1980 to 1985, a very high rate of HBV infection was observed in MSM, accounting for 20% of all reported cases of infection.[52–54] Multiple sexual partners, anal-receptive intercourse, and duration of sexual activity were the most common factors associated with HBV acquisition in the MSM population. Current rates of HBV infection in this population have fallen and are estimated to be about 8%, possibly as a result of modifications of sexual behavior in response to HIV. Similar to heterosexuals, the use of condoms in this population has reduced the risk of sexual transmission.

BLOOD AND BLOOD PRODUCTS

Although the risk of transfusion-associated HBV infection has been greatly reduced with the screening of blood (tests for HBsAg and anti-HBc) and the exclusion of donors who engage in high-risk activities, it is estimated that 1 of 50,000 transfused units could transmit HBV infection.[52–54]

PERINATAL TRANSMISSION

Early-childhood exposure and perinatal exposure are additional modes of transmission of HBV infection. High serum concentrations of virus have been linked with increased risk of transmission by vertical routes (and needlestick exposure). Infants born to HBeAg-positive mothers with high viral replication (>80 pg/mL) have a 70% to 90% risk of perinatal HBV acquisition compared with a 10% to 40% risk in infants born to mothers infected with HBV who are HBeAg-negative.[52–54] Infection generally occurs via inoculation of the infant at the time of birth or soon thereafter, and even with active and passive immunization, 10% to 15% of babies acquire HBV infection at birth.

In developing countries with high prevalence rates and in regions of the United States with high endemicity, children born to HBsAg-positive mothers with HBV are at risk for acquiring HBV infection in the perinatal period, with infection rates reported to be between 7% and 13%.[48–50] In addition, children of HBsAg-positive mothers who are not infected at birth remain at very high risk of early-childhood infection, with 60% of those born to HBsAg-positive mothers becoming infected by the age of 5 years. The mechanism of the later infection, which is neither perinatal nor sexual, is not known however. Although HBsAg is detectable in breast milk, breast-feeding is not believed to be a primary mode of HBV transmission.

INJECTION DRUG USE

Recreational and illicit drug use in the United States and globally is a significant mode of HBV transmission, accounting for approximately 23% of all patients.[52–54] The risk increases with the duration of injection drug use; thus, serologic markers of ongoing or prior HBV infection are usually positive after 5 years of drug use.

OTHER MODES OF TRANSMISSION

Other risk factors for transmission of HBV include working in a healthcare setting, receiving blood transfusion (not properly screened) and dialysis, receiving acupuncture and tattoos from contaminated needles, traveling to regions of the world endemic for HBV infection, and living in correctional facilities or prisons.[52–54] Sporadic cases of HBV transmission have been attributed to nonpercutaneous transmission by way of small breaks in the skin, biting, or mucous membranes. Although HBsAg is found in bodily fluids (e.g., saliva, tears, sweat, semen, vaginal secretions, breast milk, cerebrospinal fluid, ascites, pleural fluid, synovial fluid, gastric juice, and urine), only semen, saliva, and serum actually contain infectious HBV.[55–58]

Pathogenesis

Similar to HAV infection, clinical observations suggest that host immune responses are more important than virologic factors in the pathogenesis of liver injury. Host cellular and humoral immune responses are linked to T lymphocytes, which enhance viral clearance from hepatocytes and cause liver injury.[55,56]

Diagnosis

The presence of HBsAg in serum is diagnostic for HBV infection. In 5% to 10% of acute cases in which the HBsAg levels fall below sensitivity thresholds of current assays, the presence of IgM anti-HBc in serum confirms a recent acute HBV infection. Another highly reliable marker of active HBV replication and diagnosis is the presence of HBV DNA in serum through qualitative or quantitative assays, detectable early during the course of acute HBV infection.[57–59] Persistent levels of HBV DNA indicate ongoing infection and a high degree of active viral replication and infectivity.

Serology

Antigens and antibodies associated with HBV infection include HBsAg and antibody to HBsAg (anti-HBs), hepatitis B core antigen (HBcAg), antibody to HBcAg (anti-HBc), hepatitis B e antigen (HBeAg), and antibody to HBeAg (anti-HBe). The serologic markers that differentiate between acute, resolving, and chronic infection are HBsAg, anti-HBc, and anti-HBs. HBeAg and anti-HBe screening are used for the management of patients with chronic infection.[49] Serologic patterns, general definitions, and diagnostic criteria of HBV infection are depicted in Table 80-3. Within the first several weeks after exposure (range: 2–10 weeks), HBsAg appears in the blood and is present for several weeks before serum concentrations of aminotransferases increase and symptoms (Fig. 80-4).[57–58] Clinical illness usually follows HBV exposure by 1 to 3 months. HBsAg can be detected in serum until the clinical illness resolves and usually becomes undetectable after 4 to 6 months. Persistence of HBsAg beyond 6 months implies progression to chronic HBV infection. The antibody to HBsAg (anti-HBs) often appears after a short "window" period during which neither HBsAg nor anti-HBs are detectable. In most patients, anti-HBs persists for years after HBV infection, conferring immunity to reinfection (see Fig. 80-4).

Table 80-3

Hepatitis B Virus: Laboratory Markers and Interpretations[55,56]

Laboratory Marker	Interpretation
Hepatitis B surface antigen (HBsAg)	Marker of infection; presence indicates person is infectious
Hepatitis B surface antibody (anti-HBs)	Past infection, or person has been vaccinated
Hepatitis B core antibody (anti-HBc)	Marker of previous or ongoing infection
IgM antibody to Hepatitis B core antigen (IgM anti-HBc)	Indicates acute infection; first reaction of the body's immune response to HBV
Hepatitis B e antigen (HBeAg)	Marker of active replication of virus and infectiveness
Hepatitis B e antibody (HBeAb or anti-HBe)	Virus is no longer replicating; predictor of long-term clearance of HBV in patients undergoing antiviral therapy
Hepatitis B virus DNA (HBV-DNA)	Indicates active replication of virus; more accurate than HBeAg; used mainly for monitoring response to therapy

Interpretation of serologic markers is described in Table 80-4. A soluble viral protein, HBeAg, is detectable early during the acute phase of the disease and persists in chronic hepatitis B infection. HBeAg is a marker of active HBV replication, and its presence correlates with circulating HBV particles. The presence of both HBeAg and HBsAg indicates high levels of viral replication and infectivity and a need for antiviral therapy. Generally, seroconversion from HBeAg to hepatitis B envelope antibody (anti-HBe) results in a reduction in HBV DNA and suggests resolution of HBV infection. Some patients may, however, continue to have active liver disease and detectable serum HBV DNA levels as a result of the presence of wild-type virus or the presence of precore or promoter mutations that impair HBeAg secretion (HBeAg-negative patients).

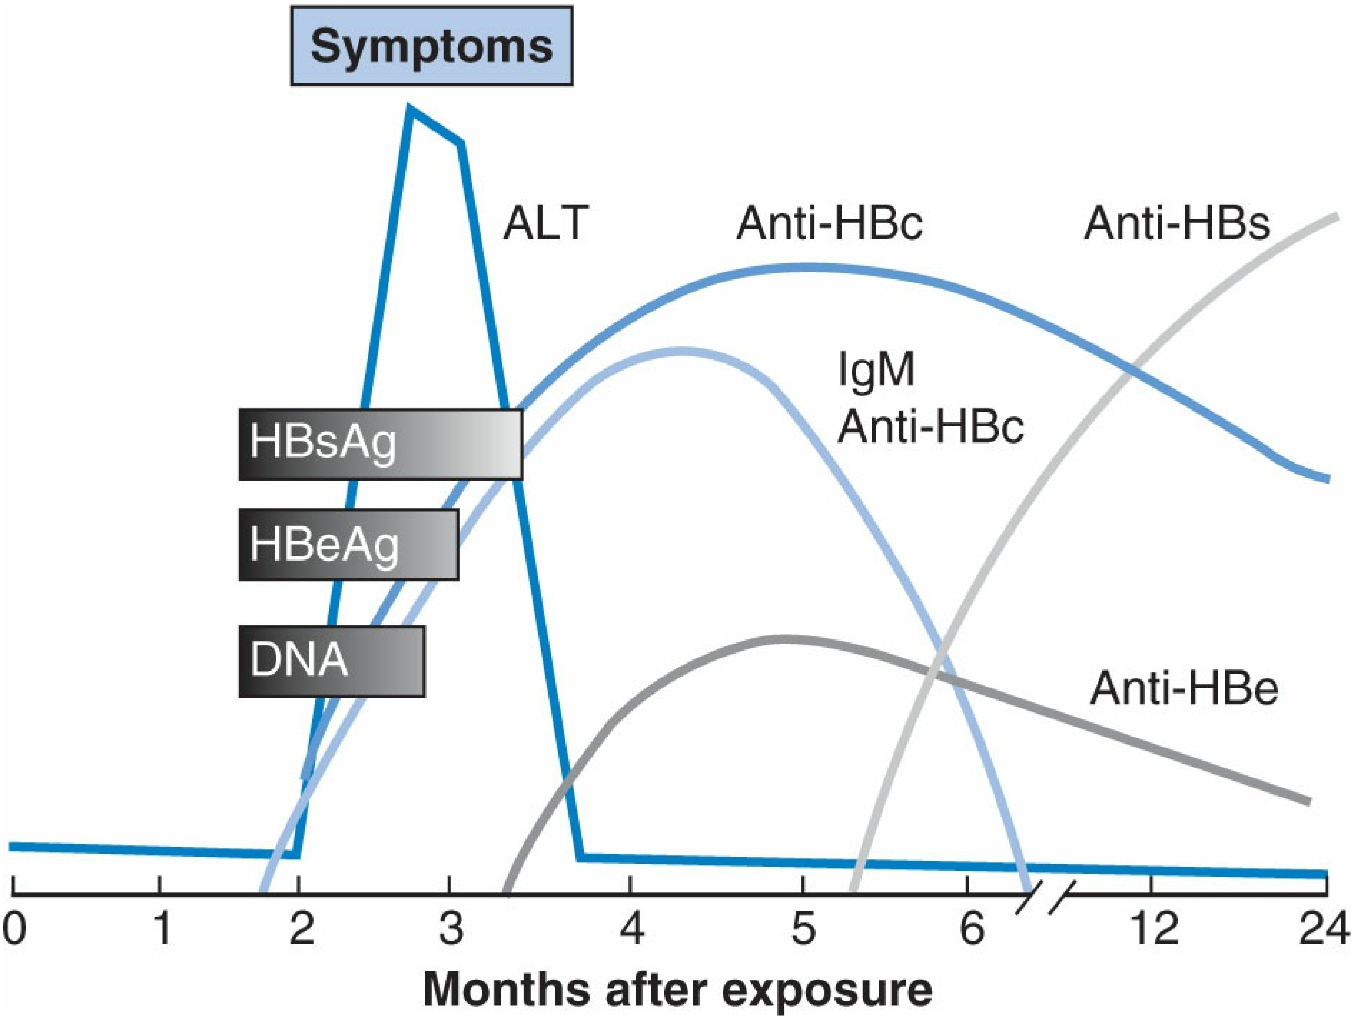

Figure 80-4 Sequence of events after acute hepatitis B virus infection with resolution. ALT, alanine aminotransferase; anti-HBc, hepatitis B core antibody; anti-HBe, hepatitis B envelope antibody; anti-HBs, hepatitis B surface antibody; HBeAg, hepatitis B envelope antigen; HBsAg, hepatitis B surface antigen; HBV DNA; hepatitis B virus DNA; IgM anti-HBc, immunoglobulin M antibody to hepatitis B core virus. Table 80-4

Hepatitis B Virus: Interpretation of Laboratory Results[45]

Laboratory Markers	Laboratory Results	Clinical Interpretation
HBsAg anti-HBc	Negative Negative	Susceptible

anti-HBs	Negative	
HBsAg anti-HBc anti-HBs	Negative Positive Positive	Immune due to natural infection
HBsAg anti-HBc anti-HBs	Negative Negative Positive	Immune due to hepatitis B vaccination
HBsAg anti-HBc IgM anti-HBc anti-HBs	Positive Positive Positive Negative	Acute infection
HBsAg anti-HBc anti-HBs	Negative Positive Negative	Interpretation unclear; 4 possibilities: 1. Resolved infection (most common) 2. False-positive anti-HBc, thus susceptible 3. "Low-level" chronic infection 4. Resolving acute infection

Hepatitis B core antigen does not circulate freely in the bloodstream and is not measured. Anti-HBc, the antibody directed against hepatitis B core antigen, is usually detected 1 to 2 weeks after the appearance of HBsAg and just before the onset of clinical symptoms, and it persists for life. The detection of IgM anti-HBc is the most sensitive diagnostic test for acute HBV infection. During the recovery phase of infection, the predominant form of anti-HBc is in the IgG class. The presence of this antibody suggests prior or ongoing infection with HBV. Furthermore, in areas where HBV is not endemic, isolated detection of anti-HBc in a patient's serum may correlate with low levels of HBV DNA. The presence of HBV DNA may enhance the risk of transmission of HBV and progression to cirrhosis and HCC. Patients immunized against HBV do not develop anti-HBc; therefore, the presence of this antibody differentiates successful vaccination from actual HBV infection.

Natural History

Of those patients with acute HBV infection, only 1% develop FHF with associated coagulopathy, encephalopathy, and cerebral edema.[60,61] The cause of fulminant infection is a heightened immune response to the virus, in the absence of HDV or HCV coinfections. Patients with ALF often have early clearance of HBsAg, which may complicate the diagnosis, but a positive IgM antibody to hepatitis B core antigen generally confirms the diagnosis.

Four phases of HBV infection are present: immune tolerance, immune clearance, low-level replication or nonreplication phase

---

(inactive carrier), and reactivation phase. Up to 12% (average 5%) of immunocompetent patients acutely infected with HBV remain chronically infected (historically defined as detectable HBsAg in serum for 6 months or longer).[59,60] In these patients, HBsAg generally remains detectable indefinitely and anti-HBs fails to appear. The risk of chronicity after neonatally acquired infection is high (>90%), possibly because neonates have immature immune systems. Of infected neonates, 50% have evidence of active viral replication. Furthermore, patients who have a reduced ability to clear viral infections—including those receiving chronic hemodialysis, immunosuppression after transplantation, or chemotherapy, or patients with HIV infection—may have a greater risk for developing chronic HBV infection.[40,62] Ultimate outcomes are linked with the presence or absence of viral replication and by the severity of liver damage. Approximately 50% of all chronic carriers have ongoing viral replication, especially with elevated aminotransferases, and 15% to 20% of these develop cirrhosis within 5 years.[40–43,62] Spontaneous loss of HBeAg (7%–20%/year) has been reported, possibly as a result of the use of antiviral therapy, whereas loss of HBsAg occurs less frequently (1%–2%/year). In general, chronic carriers remain infected throughout their life.[40–43,62] Five-year survival rates decline depending on the severity of disease (55% survival with cirrhosis).[62] Asymptomatic HBV carriers tend to have mild disease manifestations with few complications, even with a long period of follow-up. Finally, the risk of HCC is increased up to 300 times in chronic carriers with active viral replication (HBeAg positive).[62,63]

Clinical Manifestations

CASE 80-4

QUESTION 1: W.H. is a 35-year-old man who developed nausea, vomiting, anorexia, scleral icterus, and jaundice within the past month. Within the past week he became increasingly lethargic, confused, and disoriented, and lapsed into a grade IV coma. He is admitted to the ED, intubated, and transferred to the intensive care unit.

W.H.'s social history is significant for IV drug use for the past 10 years and alcohol abuse (none for the previous 5 years). Physical findings include an older-than-age-appearing, hypertensive (blood pressure, 158/99 mm Hg), bradycardic (heart rate, 58 beats/minute) man in respiratory distress (respiratory rate, 26 breaths/minute) with severe jaundice, scleral icterus, and decreased hepatic dullness to percussion (reduced hepatic mass). He shows sluggish pupillary response and increasing muscle tone; neurologic examination reveals him to be stuporous and nonarousable.

The laboratory evaluation shows the following results:

Hct: 42%
Hgb: 14 g/dL
Platelets: 85,000/μL
PT: 25.8 seconds
International normalized ratio (INR): 3.8
AST: 555 units/L
ALT: 495 units/L
Alkaline phosphatase: 101 units/mL
Total bilirubin: 8.4 mg/dL

HBV DNA: 6,000,000 IU/mL

Hepatitis serologic tests are positive for HBsAg, HBeAg, IgM anti-HBc, and HBV DNA. IgM anti-HAV, IgM anti-HDV, and anti-HCV are negative. STAT blood gases reveal a metabolic acidosis with a compensatory respiratory alkalosis. W.H.'s serum creatinine is 1.8 mg/dL with a recent reduction in urine output.

What clinical findings does W.H. have that support the diagnosis of acute hepatitis and ALF?

The clinical features of acute HBV infection are similar to those described for HAV infection. W.H.'s initial symptoms included a recent history of nausea, vomiting, anorexia, scleral icterus, and jaundice. These are consistent with diagnosis of acute hepatitis B. His serologies, notably a positive IgM anti-HBc and HBV DNA, also support this diagnosis.

ACUTE LIVER FAILURE

The most significant complication of acute HBV infection is ALF, widely defined as a coagulation abnormality (INR >1.5) and any degree of mental alteration (encephalopathy) in a patient of less than 26 weeks' duration.[61,64] He has hepatic encephalopathy, lethargy, confusion, coma, coagulopathy, hemodynamic instability, declining liver function, and acidosis. Patients with ALF often have cerebral edema (80% mortality rate), a complication of a disrupted blood–brain barrier that allows protein-rich fluid to cross into the extracellular spaces of the brain tissue leading to edema and increased intracranial pressure (ICP) or intracranial hypertension (vasogenic model). Clinical symptoms (sluggish pupillary response and increasing muscle tone) develop when the ICP is greater than 30 mm Hg.[61,65–67] Cerebral edema in the confinement of the cranial vault raises the ICP, which may reduce intracerebral perfusion. The edema can result in cerebral ischemia if the cerebral perfusion pressure (systemic blood pressure minus ICP) is not maintained at greater than 40 mm Hg. Of note, intracranial hypertension in ALF is related to the severity of encephalopathy. Cerebral edema is rarely reported in patients with grade I or II encephalopathy but occurs in up to 75% of patients with grade IV coma.[68] Diagnostic head imaging tests (computerized tomography), elevation of the head of the bed, and intubation (and subsequent hyperventilation) may be necessary medical interventions in this setting.

W.H. has symptoms of cerebral edema and may benefit from 100 to 200 mL of a 20% solution of mannitol (0.5–1.0 g/kg) administered by rapid IV infusion to induce an osmotic diuresis with a subsequent decrease in ICP. The dose may be repeated at least once after several hours provided serum osmolality has not exceeded 320 mOsm/L.[67,68] Because W.H. also has a blood pressure of 158/99 mm Hg and a heart rate of 58 beats/minute, and is at risk for intracranial hemorrhage, an ICP monitoring device should be placed.[67,68] Although placement of this device is invasive and bleeding is a potential complication, ICP monitoring devices provide important prognostic information. Patients with a cerebral perfusion pressure of greater than 40 mm Hg that is refractory to mannitol therapy are not candidates for liver transplantation. W.H. also has a coagulopathy typical of ALF. Decreased levels of clotting factors II, V, VII, IX, and X normally synthesized by the liver account for his prolonged PT and elevated INR.[64–66] Recombinant activated factor VII has been used selectively in patients with ALF, but is usually reserved for administration before any invasive procedures. In addition, consumption of clotting factors by low-grade disseminated intravascular coagulation is common in ALF. W.H. is also thrombocytopenic and at risk for GI ulceration.[68,69] A platelet transfusion should be considered if his counts drop to less than 10,000/μL. Because he is not actively bleeding, fresh-frozen plasma is not indicated at this time.[68,69]

W.H. also should be monitored for cardiovascular and renal abnormalities as a result of his ALF.[64,67] Although W.H. is hypertensive, most patients with ALF are hypotensive and hypovolemic and present with interstitial edema owing to low levels of oncotic proteins. Functional renal failure, also known as hepatorenal syndrome or acute tubular necrosis, occurs in 43% to 55% of patients with ALF.[69,70] In hepatorenal syndrome, renal blood flow is reduced, renin and aldosterone levels are increased, and levels of atrial natriuretic factor are unchanged.[70]

As seen in W.H., patients may develop acid–base disturbances, including respiratory alkalosis as a result of central nervous system-mediated hyperventilation or a lactic acid-induced metabolic acidosis.[66,69] Hyponatremia, hypokalemia, hypocalcemia, hypomagnesemia, hypoglycemia, seizures, infections (bacterial or fungal), and pancreatitis are additional findings associated with ALF. Thus, sodium, potassium, calcium, magnesium, blood glucose, and amylase should be monitored closely in W.H.[66,69] Prophylactic antimicrobial therapy reduces the incidence of infections in selected groups of ALF patients, but no survival benefit has been demonstrated.[66,69] Therefore, if antibiotics are not initiated, surveillance for infection (via chest radiography and blood, urine, and sputum cultures) should be undertaken while having a low threshold for initiating appropriate antibacterial or antifungal therapy. Finally, pulmonary complications (hypoxemia, aspiration, adult respiratory distress syndrome, and pulmonary edema) may also occur in patients with ALF.[69,70]

PROGNOSIS

CASE 80-4, QUESTION 2: What is W.H.'s prognosis?

Although the incidence of ALF is less than 1%, the prognosis for these patients is poor once encephalopathy has developed.[70,71] Survival depends on the etiology and degree of hepatic destruction, the ability of the remaining liver cells to regenerate, and the management of complications that may develop during the course of illness. Survival rates often depend on the etiology of ALF. Non-A, non-B (NANB) hepatitis and halothane or drug hepatotoxicity have been associated with worse survivals compared with those with hepatitis A, hepatitis B, or acetaminophen overdose.[71] Age younger than 14 years, worsening grade of encephalopathy, reduced liver size, and significantly abnormal LFT values (e.g., serum bilirubin, aminotransferases, alkaline phosphatase, PT, and serum albumin) are also poor prognostic indicators in patients with ALF.[70,71] Because W.H. has evidence of encephalopathy, cerebral edema, and abnormal LFT values, he has a poor prognosis.

TREATMENT

CASE 80-4, QUESTION 3: Outline an appropriate treatment plan for W.H.'s ALF.

The primary therapy for ALF is supportive care for the comatose patient. Systemic therapies with heparin, prostaglandin, or insulin and glucagon have shown limited efficacy.[66] Blood or plasma exchange, hemodialysis, or other methods implemented to detoxify the blood or improve the coma grade do not result in long-term benefits if liver mass is not reconstituted as well. Thiopental may be useful in lowering ICP, but corticosteroids and prolonged hyperventilation are of no value.[66,69] W.H. could benefit from prophylactic histamine H_2-blockers because they have been shown to reduce the incidence of upper GI hemorrhage.[66] The role of proton-pump inhibitors has not been clearly defined, although limited data have also supported their role in this setting. Blood products (packed red blood cells, fresh-frozen plasma, or platelets) should be given as needed if W.H. develops active bleeding, and pulmonary artery monitoring should be implemented to guide management of intravascular volume and gas exchange. W.H. should be closely monitored for additional complications, especially cardiac abnormalities (arrhythmias), hemodynamic changes, renal failure, acidosis, pulmonary complications, and sepsis.

In cases in which prognostic information indicates less than 20% chance of survival without transplantation, liver transplantation is indicated. In patients with acetaminophen poisoning resulting in ALF, a pH less than 7.3, a PT longer than 100 seconds, and a serum creatinine greater than 3.4 mg/dL, with grade III or IV encephalopathy, usually require transplantation.[71] Other causes of ALF, a PT longer than 50 seconds, or any three of the following variables (irrespective of grade of encephalopathy)—age younger than 10 years or older than 40 years; liver failure caused by NANB hepatitis, halothane-induced hepatitis, or idiosyncratic drug reactions; duration of jaundice before encephalopathy more than 7 days; or serum bilirubin greater than 17.5 mg/dL—indicate a need for transplantation.[70,71] Although these criteria continue to be used worldwide, they are less reliable in patients with moderate illness; sensitivity is acceptable although specificity is poor. Therefore, other models and surrogate markers have emerged to predict survival, such as the model for end-stage liver disease, Acute Physiology and Chronic Health Evaluation

II scoring system, and biomarkers such as Gc protein (also known as vitamin D_3-binding protein), α-fetoprotein, or troponin.[71] To date, none of these methods have been flawless in their ability to accurately predict outcome in ALF.

Coinfection with Human Immunodeficiency Virus (HIV)

CASE 80-4, QUESTION 4: What is the likelihood for HIV and HBV coinfection for W.H.?

Coinfection with other viruses has been reported in patients with HBV infection. For example, markers of prior or active HBV infection are present in more than 80% of patients with acquired immunodeficiency syndrome, with approximately 10% of these cases seropositive for HBsAg.[42,43] HIV has also been reported to coexist in up to 13% of patients with chronic HBV infection.[42,43] Compared with patients with HBV infection alone, patients coinfected with HBV and HIV have significantly higher levels of viral replication, lower ALT levels, and less severe histologic disease. HBV infection does not reduce survival in HIV-positive patients; however, because these patients live longer, hepatic decompensation and manifestations of HBV may occur.[50,52]

Prevention of Hepatitis B

Alterations in sexual behavior, screening of high-risk patients or settings (e.g., STD and HIV testing at treatment facilities, drug abuse treatment and prevention settings, healthcare settings targeting services to IV drug users, healthcare settings targeting services to MSM, and correctional facilities) and blood products, developing needle exchange programs, and cultural outreach and education may have an impact on HBV transmission. The goals of preventive therapy should be to identify all persons who require immunoprophylaxis for the prevention of infection and provide long-term protection through vaccination to decrease the risk of chronic HBV infection and its subsequent complications, as well as minimizing adverse effects and cost of therapy.

PRE-EXPOSURE PROPHYLAXIS

CASE 80-5

QUESTION 1: P.G., a 55-year-old nursing student, is going to start her clinical rotations. She has no history of hepatitis and has not yet been immunized. She is 5 feet 2 inches and weighs 80 kg. What prophylactic regimen should P.G. receive to prevent hepatitis secondary to HBV?

Manufactured using recombinant DNA technology, Recombivax HB (10 mg HBsAg/mL) and Engerix-B (20 mg HBsAg/mL) are yeast-derived HBV vaccines that induce an immunologic response.

Because P.G. will come in contact with potentially infectious bodily secretions during her rotations, she should be immunized against hepatitis B with either Recombivax HB or Engerix-B.[72,73]

Dosing Regimen

Relative potency comparisons are not clinically important because comparative trials using Recombivax HB and Engerix-B in the recommended dosages have demonstrated equivalent immunogenicity and tolerability. P.G. can be immunized with either product, provided she receives the manufacturer's recommended dosage with each injection. Hepatitis B vaccine is administered as an IM injection in the deltoid muscle of adults and children or in the anterolateral thigh muscle of neonates and infants. The immunogenicity of hepatitis B vaccine is significantly lower when injections are given in the buttocks, probably because the greater amount of fat tissue in the buttocks inhibits interfacing of vaccine and antigen-recognition leukocytes. The results of a small vaccination series suggest that healthy adults who do not respond to hepatitis B vaccine injection to the buttocks have a significantly higher response when vaccinated in the arm. P.G. should be immunized with either Recombivax HB (10 mcg) or Engerix-B (20 mcg) administered as a 1-mL IM injection in the deltoid muscle.[74–76]

Efficacy

Recombinant yeast-derived vaccines (e.g., Recombivax HB, Engerix-B) produce similar results.[71–73] A protective antibody response has been defined as anti-HBs levels of at least 10 IU/mL.[63,77] This threshold was derived from early HBV vaccine trials in homosexual men, in which vaccine recipients with serum antibody levels of at least 10 sample ratio units (SRUs) were protected from HBV infection.[74,75] A serum antibody level of 10 SRU is roughly equivalent to 10 milli-international units/mL when the international standard is used. For this reason, an anti-HBs level of at least 10 IU/mL is considered a protective antibody titer and is the standard used by the ACIP. Although HBV infections have occurred in vaccine recipients with a detectable immune response, almost all infections have been asymptomatic, identified only through the presence of anti-HBc. These infections have been limited largely to patients with no response or a poor response to vaccination.[53]

Nonresponders

CASE 80-5, QUESTION 2: P.G. has completed her three-dose vaccination series with Engerix-B. Routine hepatitis serology testing, performed before volunteering for a drug study, reveals that P.G. is anti-HBs negative. Why did P.G. not respond to the hepatitis B vaccine, and how should she be managed?

Two important determinants of vaccine efficacy appear to be the age at vaccination and underlying immune function. In healthy recipients, the immune response to vaccination decreases with advancing age. In one study, 99% of patients aged 0 to 19 years, 93% of those aged 20 to 49 years, and 73% of those older than 50 years of age achieved protective anti-HBs levels (>10 SRU) after three doses of the hepatitis B vaccine.[53] Immunocompromised patients, including those receiving hemodialysis, those infected with HIV, or children receiving cytotoxic chemotherapy, respond poorly to the hepatitis B vaccine. Patients who smoke, or are obese, also have a reduced response.[74,75] P.G. has two risk factors for a poor response to the hepatitis B vaccine: She is older than 50 years of age, and she is moderately obese (ideal body weight for her height is 50 kg).

Vaccine recipients who respond poorly to hepatitis B vaccine have been classified either as hyporesponders who can probably be protected by additional doses of vaccine or as true nonresponders. Patients with inadequate initial response to the HBV vaccine series should be revaccinated. Of the hyporesponders (anti-HBs levels <10 IU/mL), 50% to 90% achieve a protective level after a single booster injection or after repeating the entire three-dose series.[76,77] Of patients not responding to a primary vaccination series with Engerix-B, 60% produced an immune response after a three-dose series with HBVax II (Recombivax), suggesting a repeat course with the alternative HBV vaccine may be a reasonable approach in some patients.[76,77] Revaccination of nonresponders (no detectable anti-HBs) is less successful, and protective levels, if achieved, are not sustained.[53] True nonresponders to HBV vaccination are rare in the immunocompetent population, and these persons may have a genetic predisposition toward nonresponsiveness.[76,78] P.G. should be revaccinated with a booster dose of hepatitis B vaccine. Her anti-HBs levels can be rechecked 1 month after the injection. If she still has not responded, it is reasonable to administer an additional two injections to complete a second vaccination series.

Interchangeability of Hepatitis B Virus Vaccines

CASE 80-6

QUESTION 1: T.M., a 32-year-old hospital laboratory technician, received the first two doses of hepatitis B vaccine with Recombivax HB. He has relocated recently and is due for the third injection. The employee health service at his new job uses only Engerix-B for hepatitis B vaccination. Can hepatitis B vaccines produced by different manufacturers be used interchangeably?

Although it is recommended that patients receive the complete vaccination series with the same product, it is not absolutely necessary. To determine whether a hepatitis B vaccination series initiated with Recombivax HB could be completed with Engerix-B, healthy adults received 10 mcg of Recombivax HB at baseline and 1 month. At 6 months, the subjects were randomly assigned to receive either Engerix-B 20 mcg or Recombivax HB 10 mcg. One month after the third dose, 100% of those who had received Engerix-B and 92% of those who had received Recombivax HB had protective anti-HBs levels.[72,73]

Chan et al.[78] studied the booster response to either recombinant hepatitis B vaccine or plasma-derived vaccine in children who had been vaccinated originally with the plasma-derived product (Heptavax-B). Children were randomly assigned to receive either 5 mcg of the plasma-derived vaccine or 20 mcg of Engerix-B. One month after the booster injection, all vaccine recipients had significant elevations in their anti-HBs titers, suggesting recombinant hepatitis B vaccines elicit an adequate booster response in persons who originally received the plasma-derived vaccine. According to the ACIP, the immune response from one or two doses of a vaccine produced by one manufacturer, when followed by subsequent doses from a different manufacturer, is comparable with that resulting from a full course of vaccination with a single vaccine.[53]

T.M. may complete the hepatitis B vaccine series with Engerix-B provided he receives the recommended dosage of 20 mcg administered as a 1-mL IM injection to the deltoid region.

Duration of Response

CASE 80-6, QUESTION 2: Does T.M. require a booster injection for sustained protection from HBV infection?

The duration of vaccine-induced immunity has been evaluated in many long-term studies.[79–82] The duration of detectable anti-HBs appears proportional to the peak antibody response achieved after

---

vaccination, and protective anti-HBs levels were sustained in 68% to 85% of patients receiving the plasma-derived HBV vaccine from 6 to 12 years.[79–82] Importantly, the protective efficacy of the HBV vaccine in these trials was high, even in patients with anti-HBs levels <10 IU/mL. HBsAg was only rarely detected, and most HBV events consisted of asymptomatic seroconversion to anti-HBc. These studies suggest that successful HBV vaccination is associated with long-lasting protection without the need for additional booster doses for up to 12 years.

The mechanism of sustained protection from HBV, despite low or undetectable anti-HBs levels, is thought to be related to the phenomenon of immunologic memory in previously sensitized B lymphocytes. This amnestic response, in combination with the long incubation period of HBV, may allow the synthesis of protective antibodies sufficiently quickly to block infection in patients rechallenged with HBV.[77]

In summary, no need exists for routine administration of HBV vaccine booster doses to immunocompetent persons after successful vaccination. Immunocompromised patients may require a persistent minimal level of protective antibody, and the ACIP does recommend annual antibody testing for patients receiving chronic hemodialysis with administration of a booster dose when antibody levels are less than 10 IU/mL.[53] Based on available evidence, T.M. does not require a scheduled booster dose of hepatitis B vaccine.

Indications

CASE 80-6, QUESTION 3: Why is it appropriate for T.M. to be vaccinated with hepatitis B vaccine, and who else should be vaccinated with this vaccine?

The ACIP has recommended pre-exposure hepatitis B vaccination for the following high-risk groups: Healthcare workers with exposure to blood, staff of institutions for the developmentally disabled, hemodialysis patients, recipients of blood products, household and sexual contacts of HBV carriers, international travelers to HBV-endemic areas, injecting drug users, sexually active homosexual men, bisexual men, and inmates of long-term correctional facilities.[53,83,84] Because T.M. is a hospital laboratory technician, he is at high risk for exposure to HBV and should be vaccinated.

Universal Hepatitis B Vaccination

In addition to the previously listed high-risk groups, all infants should receive hepatitis B vaccination. The practice of vaccinating only high-risk persons has resulted in little impact on the incidence of HBV disease. Populations at risk for HBV disease (injecting drug users, persons with multiple sexual partners) generally are not vaccinated before they begin engaging in high-risk behaviors. In addition, many persons who become infected have no identifiable risk factors for infection and thus would not be recognized as candidates for vaccination. A program designed to immunize children before they initiate high-risk behaviors is likely to have a greater impact in reducing the incidence of HBV infection. As a means to achieve this goal, the hepatitis B vaccine now is incorporated into the existing pediatric vaccination schedule. The first dose is administered during the newborn period (preferably before the infant is discharged from the hospital) but no later than 2 months of age.[52,53] The recommended vaccination schedule is shown in Table 80-5.

CASE 80-7

QUESTION 1: R.M. is a mother of two children aged 11 years and 2 months. Her infant daughter just received a second dose of hepatitis B vaccine as part of her routine well-baby care. R.M. wonders whether her son, who did not receive the hepatitis B vaccine during his normal childhood immunizations, should receive the vaccine now.

Table 80-5

Recommended Schedules of Hepatitis B Vaccination for Infants Born to HBsAg

(−) Mothers[52,53]

Hepatitis B Vaccine	Age of Infant
Option 1	
Dose 1	Birth (before hospital discharge)
Dose 2	1–2 months[a]
Dose 3	6–18 months[a]
Option 2	
Dose 1	1–2 months[a]
Dose 2	4 months[a]
Dose 3	6–18 months[a]

[a] Hepatitis B vaccine can be administered simultaneously with diphtheria–tetanus–pertussis, Haemophilus influenzae type b conjugate, measles–mumps–rubella, and oral polio vaccines.

The Centers for Disease Control and Prevention (CDC) has addressed the issue of immunizing children and adolescents born before 1991 who are potentially at risk for hepatitis B infection. The current recommendations suggest that adolescents who have not received three doses of hepatitis B vaccine should initiate or complete the series at ages 11 to 15 years. A schedule of 0, 1 to 2, and 4 to 6 months is recommended.[52,53] It is anticipated that universal vaccination of all infants and previously unvaccinated adolescents aged 11 to 12 years, in addition to ongoing immunization of high-risk persons, will reduce the incidence of acute hepatitis B infection, hepatitis B-associated chronic liver disease, and HCC. R.M.'s son should receive either Recombivax HB 5 mcg or Engerix-B 10 mcg IM in the deltoid with repeat doses 1 to 2 months and 4 to 6 months from the initial injection.

Adverse Effects

HBV vaccination generally has been well tolerated. The most common side effect is pain at the injection site, observed in 3% to 29% of patients. Transient febrile reactions (defined as temperature >99.9°F) occur in less than 6% of recipients, and other reactions, including nausea, rash, headache, myalgias, and arthralgias, are observed in less than 1% of recipients. Ongoing monitoring of vaccine safety by the FDA and CDC is assessed through the Vaccine Safety Datalink project and Vaccine Adverse Events Reporting System.[52,53] On the basis of these reporting systems, additional "causal" adverse effects associated with vaccination include anaphylaxis (1 case/1.1 million vaccine doses), Guillain–Barré syndrome, and multiple sclerosis. Additional rare adverse events that have been reported but remain to be validated are chronic fatigue syndrome, neurologic disorders (leukoencephalitis, optic neuritis, and transverse myelitis), rheumatoid arthritis, type 1 diabetes, and autoimmune disease.

POSTEXPOSURE PROPHYLAXIS

Percutaneous Exposure

CASE 80-8

QUESTION 1: K.N., a 26-year-old medical student, presents to the ED after accidentally sticking herself with a contaminated needle while drawing blood from an HBsAg-positive patient. K.N. was not vaccinated previously and had no known prior episodes of hepatitis or liver disease. Her tetanus status is current. She weighs 56 kg. How should K.N. be treated for percutaneous exposure to hepatitis B?

After exposure to HBV, prophylactic treatment with hepatitis B vaccination and possibly passive immunization with hepatitis B immunoglobulin (HBIG) should be considered.[53] The ACIP recommends postexposure immunoprophylaxis after hepatitis B exposure. K.N.'s percutaneous exposure warrants active immunization with HBV and passive immunization with HBIG. The source of K.N.'s exposure is HBsAg positive, and K.N. had not been vaccinated previously with the hepatitis B vaccine. She should receive a single dose of HBIG 0.06 mL/kg (3.4 mL) as an IM injection in either the gluteal or deltoid region as soon as possible after exposure, preferably within 24 hours. HBIG is prepared from plasma of persons preselected for high-titer anti-HBs. The ratio of anti-HBs of HBIG in the United States is 1:100,000 as determined by radioimmunoassay. HBIG is superior to immunoglobulin in the prevention of hepatitis B infection after percutaneous exposure. K.N. also should receive active immunization with IM hepatitis B vaccine (at a separate site) simultaneously with HBIG. The second and third doses should be given 1 month and 6 months later. Passively acquired antibodies against HBV from HBIG or immunoglobulin will not interfere with active immunization via hepatitis B vaccine.[83]

If the HBsAg status of the donor source of a percutaneous exposure is unknown, recommendations for prophylaxis of HBV infection depend on whether the donor source is at high risk or at low risk for being HBsAg positive. High-risk donor sources include homosexual men, IV drug abusers, patients undergoing hemodialysis, residents of mental institutions, immigrants from endemic areas, and household contacts of HBV carriers.

Sexual Exposure

CASE 80-9

QUESTION 1: G.G. is a 20-year-old construction worker who had sexual contact with a partner who recently found out she was HBsAg positive. What are the current recommendations for a person who has had sexual contact with an HBsAg-positive person?

Sexual transmission of HBV is an important cause of HBV infection, accounting for approximately 30% to 60% of all new cases annually.[42,43,62] Passive immunization with a single 5-mL dose of HBIG was found highly effective in preventing HBV infection after sexual exposure when compared with a control globulin (with no anti-

HBs activity).[63,83] The CDC recommends that susceptible persons exposed to HBV through sexual contact with a person who has acute or chronic HBV infection should receive postexposure prophylaxis with 0.06 mL/kg of HBIG as a single IM dose within 14 days of the last exposure.[19,83] Patients also should receive the standard three-dose immunization series with hepatitis B vaccine beginning at the time of HBIG administration.[53]

Perinatal Exposure

CASE 80-10

QUESTION 1: S.L., a 3.2-kg boy, was just born to an HBsAg-positive mother. Is S.L. at risk for acquiring HBV infection, and how should he be treated?

In many Asian and developing countries, perinatal (vertical) transmission accounts for most HBV infections. Infants born to HBV-infected mothers have a greater than 85% risk of acquiring HBV during the perinatal period. Of those who become infected, 80% to 90% become chronic HBsAg carriers.[62,84] Although fulminant cases have been reported, most hepatitis infections in neonates are asymptomatic. Despite the usually innocuous initial disease, significant adverse consequences are associated with chronic HBsAg carriage in neonates. Chronic hepatitis B infection is associated with chronic liver disease and has been clearly implicated as a major risk factor in the development of primary HCC.[62,63]

Mothers who are chronic carriers of HBV can transmit HBV to their infants. The risk is related to the presence of HBsAg and HBeAg (suggesting a high degree of viral replication and infectivity). The likelihood that S.L. will develop HBV infection is high. S.L. requires immediate therapy with HBIG to provide immediate high titers of circulating anti-HBs, and simultaneous vaccination with hepatitis B vaccine to induce long-lasting protective immunity. Screening pregnant women for the presence of HBeAg and administration of HBIG and hepatitis B vaccine is 85% to 98% effective in preventing HBV infection and the chronic carrier state.[63,77,83] This compares with a 71% efficacy rate for administration of HBIG alone. Simultaneous administration of HBIG and hepatitis B vaccine does not adversely affect the production of anti-HBs in neonates.[52,53,63,83]

Infants born to mothers who are HBsAg-positive should receive simultaneous IM injections of the appropriate doses of hepatitis B vaccine (Table 80-5) and HBIG (0.5 mL) within 12 hours of birth. The injections should be administered at separate sites. S.L. should receive HBIG (0.5 mL) as soon as possible after birth, administered as an IM injection. He also should receive 0.5 mL of either Recombivax HB (5 mcg) or Engerix-B (10 mcg) as an IM injection at a separate site.

CASE 80-10, QUESTION 2: What would the management plan be if the HBsAg status of S.L.'s mother was unknown?

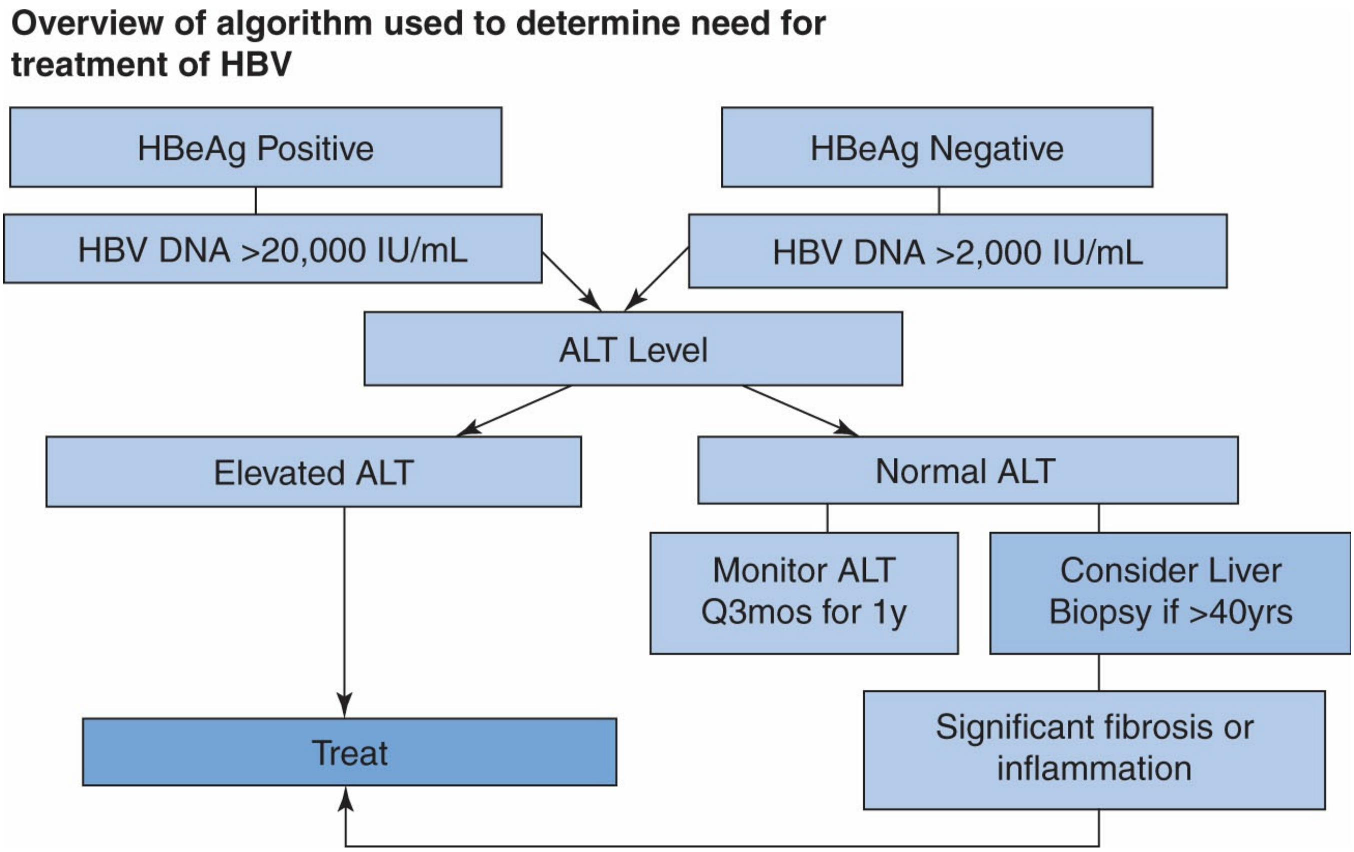
The ACIP has developed recommendations for the prevention of perinatal HBV infection. This includes the routine testing of all pregnant women for HBsAg during an early prenatal visit. HBsAg testing should be repeated late in the pregnancy for women who are HBsAg negative, but who are at high risk of HBV infection or who have had clinically apparent hepatitis. Women admitted for delivery who have not had prenatal HBsAg testing should have blood drawn for testing. Although test results are pending, the infant should receive hepatitis B vaccine within 12 hours of birth. If the mother is found later to be HBsAg positive, her infant should receive HBIG as soon as possible within 7 days of birth. The second and third doses of vaccine should be administered at 1 and 6 months, respectively. If the mother is found to be HBsAg negative, her infant should continue to receive hepatitis B vaccine as part of the routine vaccination series.[63]

Evaluation and Management of Patients with Chronic Hepatitis B Virus Infection

CASE 80-11

QUESTION 1: E.A. is a 55-year-old woman who presents to the hepatology clinic with a recent history of mild jaundice. Her previous medical history is unremarkable except for a blood transfusion she received during childbirth in 1988. What initial and follow-up tests should be performed to assess the extent of HBV infection in E.A.?

Initially, a thorough history and physical examination should be performed with greater emphasis placed on risk factors for coinfection, alcohol use, and family history of HBV and liver cancer. Laboratory tests should include assessment of liver disease, markers of HBV replication, and screening tests for HCV, HDV, or HIV. Vaccinations for hepatitis A should also be administered as described above. The decision to perform a liver biopsy should be made based on knowledge of a patient's age, the ALT level, HBeAg status, HBV DNA levels, and additional clinical features suggestive of chronic liver disease or portal hypertension. In patients who are not initially considered for treatment (inactive HBV carriers), a guideline for follow-up based on HBeAg status is described in Figure 80-5. Periodic screening for HCC should also be performed in high-risk populations such as Asian men older than 40 and Asian women older than 50 years of age, persons with cirrhosis, persons with a family history of HCC, blacks older than 20 years of age, and any carrier older than 40 years of age with persistent or intermittent ALT or HBV DNA elevations.



Overview of algorithm used to determine need for treatment of HBV
HBeAg Positive
HBeAg Negative
HBV DNA >20,000 IU/mL
HBV DNA >2,000 IU/mL
ALT Level
Elevated ALT
Normal ALT
Monitor ALT Q3mos for 1y
Consider Liver Biopsy if >40yrs
Treat
Significant fibrosis or inflammation

Figure 80-5 Overview of algorithm used to determine treatment of hepatitis B virus.

CASE 80-12

QUESTION 1: C.R., a 48-year-old man, presents to the ED with jaundice, complaints of incapacitating fatigue, and vague intermittent abdominal pain for the past month. C.R. was diagnosed with HBV infection 12 years ago. His social history includes IV drug abuse (none in the past 2 years) and alcohol abuse (none in the past 2 years). Several weeks ago, C.R. noted darkening of his urine and yellowing of his eyes. Additionally, C.R. has a history of severe depression, managed with escitalopram.

Physical examination reveals a thin man in no apparent distress. He is afebrile, and his blood pressure, heart rate, and respiratory rate are within normal limits. Moderate scleral icterus is noted. The abdomen is soft and not distended. The liver is enlarged, nontender, and smooth with an edge palpable 5 cm below the costal margin and a span of 15 cm. The spleen is palpable. The cardiac, pulmonary, neurologic, and extremity examinations all are within normal limits.

C.R.'s laboratory evaluation is significant for the following:

Hct: 39%
Hgb: 11 g/dL
WBC count: 8.8 cells/μL
Platelets: 75,000/μL
PT: 15.4 seconds
INR: 2.1
AST: 326 units/L
ALT: 382 units/L
Alkaline phosphatase: 142 units/mL
Total bilirubin: 4.2 mg/dL
Albumin: 2.8 g/dL

Hepatitis serologic tests are positive for HBsAg, HBeAg, and anti-HBc, and negative for IgM anti-HBc, IgM anti-HAV, and anti-HCV. HBV DNA is reported as greater than 20,000 IU/mL. A liver biopsy reveals periportal inflammation as well as piecemeal and bridging necrosis. What clinical findings does C.R. have that support the diagnosis of chronic HBV infection?

The chronic occurrence of jaundice and hepatosplenomegaly with significantly elevated AST and ALT in a young patient such as C.R. is suggestive of chronic hepatitis. Although alcoholic hepatitis secondary to long-term alcohol use is consistent with these clinical features, his serologic tests are positive for HBV. Hepatitis serology with positive HBsAg and HBeAg suggests ongoing viral replication and a high degree of infectivity.

Serum concentrations of aminotransferases can range from slightly abnormal to greatly elevated, with ALT concentrations generally greater than AST. Serum bilirubin concentrations greater than 3.0 mg/dL are common, serum concentration of alkaline phosphatase usually is increased, and the PT may be prolonged. Patients such as C.R. with a prolonged PT, thrombocytopenia, and low serum albumin concentration generally have a more severe form of chronic hepatitis and can be considered to have decompensated liver disease.

Liver biopsy is important for the diagnosis, treatment, and prognosis of patients with chronic hepatitis. C.R.'s liver biopsy reveals the classic triad of periportal inflammation as well as piecemeal and bridging necrosis. The liver biopsy and hepatitis serologic test results are consistent with a diagnosis of chronic HBV infection. Treatment of chronic HBV infection requires knowledge of the natural history of the untreated disease and the potential benefits of intervention. Currently, six agents are approved by the FDA for treating chronic HBV infection.

CASE 80-12, QUESTION 2: Does C.R. require treatment for chronic hepatitis secondary to hepatitis B?

The decision to treat C.R. depends on the severity of symptoms, the serum biochemistries, and the liver biopsy results. C.R. has evidence of severe chronic HBV infection. He is symptomatic with jaundice, severe fatigue, and abdominal pain, and the results of his LFTs and HBV DNA levels suggest his disease is advanced (decreased albumin, elevated PT, low platelets). Therefore, he should be treated to reduce the replication of HBV, resolve the hepatocellular damage, and prevent long-term adverse hepatic sequelae.[62,84]

GOALS OF THERAPY

CASE 80-12, QUESTION 3: What are the goals of therapy for chronic hepatitis secondary to HBV?

Progression of chronic hepatitis to cirrhosis is likely because of continued replication of the HBV. Loss of active viral replication usually is associated with a decrease in infectivity, a reduction

---

in inflammatory cells within the liver, and a fall of serum aminotransferase activities into the normal range. The disappearance of detectable HBeAg and HBV DNA is considered an indicator of loss of active viral replication.

The goals of therapy in chronic HBV infection are to achieve sustained suppression of HBV replication and remission of liver disease.[84,85] Ultimately, achieving these goals should lead to resolving ongoing hepatocellular damage and reducing the development of cirrhosis and HCC. Clinical trials for chronic HBV infection have used the following markers as end points for successful therapy: seroconversion from HBeAg positive to HBeAg negative (with appearance of anti-HBe), reductions in serum aminotransferase activity, elimination of circulating HBV DNA, and improvement in liver histology. The elimination of HBsAg (termination of HBV carrier state) has been difficult to achieve in clinical trials. Additionally, the responses to antiviral therapy of chronic HBV can be categorized as biochemical, virologic, or histologic, and as on therapy or sustained off therapy.

DRUG THERAPY

CASE 80-12, QUESTION 4: Would initiating therapy during the acute phase of the HBV infection have benefited C.R.?

Pharmacologic interventions in the management of acute hepatitis B have been disappointing. Early studies demonstrated a transient decrease in serum aminotransferase activity and bilirubin concentration associated with corticosteroids. More recent studies, however, have resulted in a higher incidence of relapse and mortality in patients receiving corticosteroids.[85–88] Other therapies, including HBIG and interferon alpha, have been ineffective in managing acute viral hepatitis secondary to HBV.[63,84] Nucleoside and nucleotide RT inhibitors reduce HBV DNA levels in patients with chronic disease,[88–92] but their use in acute HBV infection requires further investigation. Thus, administration of antivirals during the acute phase of HBV infection is not recommended in C.R.

Interferons

CASE 80-12, QUESTION 5: What drug therapy should C.R. receive to treat chronic HBV-associated infection?

Previously, the most effective agents for treating chronic hepatitis B have been interferons (IFNs),[89,90] which appear to activate their target cells by binding to specific cell surface receptors to induce synthesis of effector proteins.[89,91] These intracellular proteins induce the antiviral, antiproliferative, and immunomodulatory actions of the IFNs. Their antiviral activity possibly arises from their ability to abate viral entry into the host cells and modulate several steps of the viral replication cycle (e.g., viral uncoating, inhibition of messenger RNA, and protein synthesis). The only FDA-approved and commercially available IFN is pegylated IFN (PegIFN-α2a, Pegasys) for the treatment of chronic HBV infection. The formulation involves adding polyethylene glycol to IFN that leads to an increased serum half-life, resulting in a prolonged antiviral effect. As a result, the frequency in administration is extended from three times weekly to once a week.

Efficacy

Pegylated Interferon

Pegylated interferons (PegIFN-α2a) have the advantage of more convenient dosing and additional viral suppression for patients with HBV. Clinical data suggest that this agent has slightly enhanced efficacy than standard IFN formulations. PegIFN-α2a 180 mcg SQ weekly monotherapy was compared with PegIFN-α2a SQ weekly plus lamivudine 100 mg PO daily or lamivudine 100 mg PO daily alone.[90] At the end of the 24-week follow-up, significantly more patients who received PegIFN monotherapy or combination therapy than those who received lamivudine monotherapy had HBeAg conversion. PegIFN-α2a (alone or in combination) resulted in HBsAg conversion in 16 patients compared with none in the lamivudine monotherapy group ($p = 0.001$). Additionally, at the end of treatment, viral suppression was most pronounced in the group that received combination therapy. Similar results were reported in HBeAg-positive patients receiving PegIFN-α2b.[91] In the only published trial performed in HBeAg-negative patients, PegIFN-α2a 180 mcg weekly ($n = 177$) was compared with either PegIFN-α2a 180 mcg weekly plus 100 mg of lamivudine ($n = 179$) or 100 mg of lamivudine alone ($n = 181$). Viral suppression was greater in the combination group, but sustained response (HBV DNA and ALT levels at week 72) was comparable in the group that received PegIFN-α2a alone (or in combination), and superior to the lamivudine monotherapy group. Loss of HBsAg occurred in 12 patients in the PegIFN groups, as compared with none in the lamivudine group. Ultimately, the addition of lamivudine to PegIFN did not improve post-therapy response rates.[92]

Dosing Considerations

The recommended dose of PegIFN-α2a, the only pegylated IFN approved for the treatment of HBV infection in the United States, is 180 mcg SQ weekly for 48 weeks.[90–92] It is possible that more severe flu-like symptoms and headache occur with thrice-weekly dosing when compared with weekly administration. In contrast, severe bone marrow suppression tends to occur less often with thrice-weekly administration.[90,91]

Predictors of Response

CASE 80-12, QUESTION 6: Would C.R. be likely to respond to PegIFN-α2a therapy?

Certain patient variables can predict the response to therapy with PegIFN-α2a. The most reliable predictor of a positive response to PegIFN-α2a in HBeAg-positive patients is pretreatment ALT and HBV DNA levels.[90–92] Patients with high pretreatment ALT levels >2 times the upper limit of normal, and HBV DNA levels less than 20 IU/mL are more likely to respond to therapy.[90–93] HBeAg seroconversion with PegIFN treatment is associated with improved survival and reduced complications. Other predictors of a positive response include a short duration of disease, negative HIV status, and a high histologic activity index as demonstrated by liver biopsy or other diagnostic tools. No consistent predictor of sustained response in patients who are HBeAg negative exists. Thus, C.R. is not a reasonable candidate for PegIFN-α therapy. His liver biopsy is consistent with chronic disease, he has high pretreatment aminotransferase levels, his HBV DNA is greater than 20,000 IU/mL, and his duration of chronic hepatitis is long.

Adverse Effects

CASE 80-12, QUESTION 7: What are some additional reasons for avoiding PegIFN-α therapy in C.R.?

Adverse effects associated with PegIFN therapy can be categorized as early side effects that rarely limit the use of PegIFN, and late side effects that may necessitate dose reduction or discontinuation of therapy altogether.[90–92] The early side effects of PegIFN therapy generally appear hours after administration and resemble an influenza-like syndrome with fever, chills, anorexia, nausea, myalgias, fatigue, and headache. Virtually all patients receiving PegIFN experience these toxicities, and they tend to resolve after repeated exposure to the drug over time. Administration of PegIFN

at bedtime may decrease the severity of early onset of the side effects. Acetaminophen can be used to treat early side effects of PegIFN therapy, but should be limited to 2 g/day to minimize the risk of hepatotoxicity. The late-onset side effects usually are observed after 2 to 4 weeks of therapy and are more serious. These toxicities, which limit the use of PegIFN, include worsening of the flu-like syndrome, alopecia, bone marrow suppression, bacterial infections, thyroid dysfunction (both hypothyroidism and hyperthyroidism), and psychiatric disturbances (emotional lability, irritability, depression, anxiety, delirium, and suicidal ideation). The use of PegIFN can also cause a flare (increase) in ALT levels in 30% to 40% of patients. These flares are considered to be a favorable prognostic indicator, but they have been reported to cause hepatic decompensation, especially in cirrhotic patients. C.R.'s history of severe depression should be considered a relative contraindication to treating him with PegIFN. Furthermore, the use of PegIFN in patients with decompensated liver disease may lead to FHF. Therefore, this agent, although approved for HBV, is not optimal for him.[90–92]

Nucleoside/Nucleotide Analogs

CASE 80-12, QUESTION 8: What other antiviral therapies are available to treat C.R.'s chronic HBV infection?

Although PegIFN-α2a have been important in the treatment of chronic HBV infection, patients included in most clinical trials represented a highly select group of chronic HBV carriers. Specifically, patients with decompensated liver disease were excluded because they often have leukopenia and thrombocytopenia as a result of hypersplenism, which limits the dose of PegIFN that can be administered. In addition to PegIFN-α2a, the FDA has approved several oral antiviral agents for treatment of chronic HBV infection (lamivudine, adefovir dipivoxil, entecavir, tenofovir disoproxil fumarate, and tenofovir alafenamide).

Lamivudine

Lamivudine (Epivir-HB) was the first oral nucleoside analog approved by the FDA for use in patients with compensated liver disease who had evidence of active viral replication and liver inflammation caused by chronic HBV infection. Nucleoside analogs represent an alternative approach to treatment in patients with decompensated liver disease.[85–87] Lamivudine, the (−) enantiomer of 3′-thiacytidine, is an oral 2′-,3′-dideoxynucleoside that inhibits DNA synthesis by terminating the nascent proviral DNA chain and interferes with the RT activity of HBV.[93–95] For chronic HBV treatment, Epivir-HB is administered as 100 mg orally daily. Lamivudine is well tolerated and reduces serum levels of HBV DNA.[85–87,93,95] Lamivudine is also used as an alternative nucleoside analog for HIV treatment and is administered at a higher dose of 600 mg orally once daily in combination with antiretrovirals.

Lamivudine Resistance

CASE 80-12, QUESTION 9: What is the risk of development of lamivudine resistance in C.R.?

Considering the high rate of viral turnover and the error-susceptible nature of the polymerase (particularly the RT), acquisition of resistance mutations is common. The most common mutation leading to lamivudine resistance is a specific point mutation in the highly conserved methionine motif of the HBV DNA polymerase.[96,97] In this mutation, the methionine residue is changed to a valine or isoleucine. These genotypic mutations in the YMDD locus associated with a reduced sensitivity to lamivudine occur after long-term therapy (e.g., 52 weeks). This motif is thought to be representative of the active site of the enzyme, similar to that associated with HIV RT, leading to lamivudine resistance.[96,97] Lamivudine-resistant HBV mutants generally are detectable after 6 months or more of continuous therapy. Integrated data from four studies show a 16% to 32% incidence at 1 year, increasing to 47% to 56%

at 2 years of therapy and 69% to 75% at 3 years of therapy.[96,97] The presence of YMDD mutants results in a loss of the clinical response, a rise in ALT levels, and worsening of hepatic histology. Reports of continued improvement despite lamivudine resistance exist, but the long-term consequences of viral resistance (including hepatic decompensation and exacerbation of liver disease) are substantial. Thus, lamivudine has limited clinical utility in patients with chronic HBV and is currently considered a second-line agent.

CASE 80-12, QUESTION 10: What other nucleoside or nucleotide therapies are available for managing C.R.'s chronic HBV infection?

Adefovir

Adefovir dipivoxil (Hepsera) was approved for the oral treatment of chronic hepatitis B in adults with evidence of either active viral replication or persistent elevations in serum aminotransferases (ALT or AST) or histologically active disease.[98–100] Adefovir dipivoxil is the oral prodrug of an acyclic nucleotide monophosphate analog, 9-(2-phosphonylmethoxyethyl)-adenine. The active drug is a selective inhibitor of numerous species of viral nucleic acid polymerases and RTs. Previously, two trials reported the efficacy of adefovir 10 mg orally once daily for the treatment of patients who were HBeAg negative[99] and HBeAg positive.[100] Adverse effects from adefovir included abdominal pain, diarrhea, dyspepsia, headaches, nausea, and nephrotoxicity.

Resistance to adefovir occurs at a much slower rate compared with lamivudine. The cumulative probability of resistance in the HBeAg-negative patient trial was estimated to be 0%, 3%, 1%, 18%, and 29% at years 1, 2, 3, 4, and 5 years, respectively.[99] In the trial with HBeAg-positive patients, resistance was estimated to be 20% at 5 years.[100] Other reports have described adefovir resistance rates as high as 20% after 2 years of treatment.[98] Risk factors for adefovir resistance appear to be suboptimal viral suppression and sequential monotherapy. Thus, adefovir should also be considered a second-line therapy for C.R.

Entecavir

Entecavir (Baraclude) is an oral acyclic guanosine nucleoside derivative with potent activity against HBV.[101–103] The drug inhibits HBV replication at three different steps: (a) the priming of HBV DNA polymerase; (b) the RT of the negative-strand HBV DNA from the pregenomic RNA; and (c) the synthesis of positive-strand HBV DNA. In vitro studies have shown that the drug is more potent than lamivudine and adefovir and is highly effective against lamivudine-resistant HBV mutants.

In two published Phase III clinical trials, the efficacy of entecavir was reported in patients with HBeAg-positive[102] and HBeAg-negative[103] hepatitis B infection. Patients with compensated liver disease who had not previously received a nucleoside analog were assigned to receive entecavir 0.5 mg, or lamivudine 100 mg orally once daily for a minimum of 52 weeks. By week 48, HBeAg-positive patients receiving entecavir had higher rates of histologic (72% vs. 62%), virologic (HBV DNA undetectable by PCR; 67% vs. 36%), and biochemical (ALT normalization; 68% vs. 60%) responses when compared with lamivudine.[102] Of note, the seroconversion rates were similar among the two treatment groups (21% vs. 18%; entecavir vs. lamivudine, respectively). No viral resistance to entecavir was detected during the study period, but follow-up data suggest a low rate of resistance (3% by week 96 of therapy).[102] The authors concluded that entecavir was as safe and had significantly higher histologic, virologic, and biochemical response rates than HBeAg-positive patients treated with lamivudine. In patients who remained HBeAg positive with low levels of HBV DNA replication, a second year of entecavir and lamivudine therapy resulted in seroconversion in 11% and 13% of patients, respectively.[101,102]

In another trial of HBeAg-negative hepatitis B infection, patients received either entecavir 0.5 mg or 100 mg of lamivudine daily for a minimum of 52 weeks. At week 48, patients receiving entecavir had significantly higher rates of histologic (70% vs. 61%; $p < 0.01$), virologic (90% vs. 72%), and biochemical (78% vs. 71%) response rates.[103] No resistance was seen among patients receiving entecavir. Safety and adverse events were similar in the two groups. Thus, C.R. could receive entecavir 0.5 mg daily. As with all of the nucleoside agents, dosage adjustments should be implemented with changes in renal function. Furthermore, entecavir may be used for lamivudine-refractory or lamivudine-resistant patients. In these patients, lamivudine should be discontinued to reduce the risk of entecavir cross-resistance. The dose of entecavir used for lamivudine-resistant patients is 1 mg orally once daily. In these patients, entecavir resistance has been reported to be 51% after 5 years of therapy. Thus, alternatives may be warranted for these patients.[104–108] In regard to histologic liver improvement, entecavir was ranked superior over tenofovir disoproxil fumarate.[109]

Tenofovir disoproxil fumarate

Tenofovir disoproxil fumarate (Viread) is approved for the oral treatment of chronic HBV.[110–112] This agent is a potent nucleotide analog that is structurally similar, yet equipotent, but less nephrotoxic than adefovir. Clinical trials in HBeAg-positive and HBeAg-negative patients with chronic HBV infection have demonstrated the efficacy of tenofovir DF. In the first Phase III trial of HBeAg-positive patients with compensated liver disease, a significantly higher proportion of tenofovir-treated patients had undetectable HBV DNA (76% vs. 13%), ALT normalization (68% vs. 54%), and HBsAg loss (3% vs. 0%) at the end of therapy. Histologic response rates and HBeAg conversion were similar between the two groups. Of note, at the end of therapy, patients in the adefovir group were switched to tenofovir DF, and any patient who had detectable HBV DNA by week 72 had emtricitabine added to their regimen with subsequent additional serologic benefit.

In the second trial, HBeAg-negative patients with compensated liver disease were given a similar regimen (300 mg of tenofovir DF or 10 mg of adefovir daily for 48 weeks).[111] By week 48, a higher percentage of tenofovir-treated patients had undetectable serum HBV DNA than those treated with adefovir (93% vs. 63%). The proportions of patients having ALT normalization (76% vs. 77%) or histologic response (72% vs. 69%) were similar. No patients in the study became HBsAg negative. Again, at week 48, patients receiving adefovir were switched to tenofovir. Patients in both groups who still had detectable HBV DNA by 72 weeks were given emtricitabine. Similar to the HBeAg-positive group, the change to tenofovir DF led to additional viral suppression in the patients initially treated with adefovir. In the previous two trials, only 7 patients were observed to have virologic breakthrough during 96 weeks of therapy, but no tenofovir-resistant HBV mutations were detected. Current guidelines suggest and clinical data support tenofovir (300 mg PO every day) as a viable first-line agent for C.R.[112] Generally, tenofovir is well tolerated, but it has been reported to cause Fanconi syndrome, renal insufficiency, osteomalacia, and a decrease in bone density.[110] Similar to other agents in this class, the dose of tenofovir DF should be adjusted based on renal function.[110–112] Recommendations for treatment of chronic HBV can be found in Table 80-6.

Table 80-6

Treatments of HBV Infection[113,116]

Treatment	Preferred as First Choice	Comments
Entecavir	Yes (unless previous history of lamivudine resistance)	High potency, high genetic barrier to resistance
Tenofovir DF	Yes	High potency, high genetic barrier to resistance
TAF	Yes	High potency, high genetic barrier to resistance
PegIFN	Yes	Less safe in pts with cirrhosis
Adefovir	No	Low genetic barrier to resistance; nephrotoxic
Lamivudine	No	Low genetic barrier to resistance

Tenofovir DF, tenofovir disoproxil fumarate; TAF, tenofovir alafenamide; PegIFN, pegylated interferon alfa-2a.

Tenofovir alafenamide

Tenofovir alafenamide, or TAF (Vemlidy), is the latest oral antiviral approved for the treatment of chronic HBV infection. It is a nucleotide prodrug that is converted to tenofovir diphosphate in a two-step process, which inhibits replication of the

HBV.[113] TAF has a similar antiviral profile as its sibling drug, tenofovir DF, but at a dose one-tenth less than 300 mg. Approved at 25 mg orally once daily, TAF exhibits greater plasma stability and more efficiently delivers tenofovir to hepatocytes and results in less tenofovir in the bloodstream, leading to improved renal (eGFR and renal tubular function) and bone safety parameters (smaller declines in spine and hip bone mineral density) compared to tenofovir DF.[113–115] Two pivotal international Phase III clinical studies (Studies 108 and 110) demonstrated TAF's efficacy among 1,298 treatment-naïve and treatment-experienced adults with chronic HBV infection over 48 weeks. Study 108 was a randomized, double-blind, active-controlled trial that showed TAF was noninferior to tenofovir DF in treatment-naïve and treatment-experienced patients with HBeAg-negative chronic HBV infection.[114] Study 110 randomized and treated 873 HBeAg-positive patients with either TAF or tenofovir DF. The study results were similar showing noninferiority to tenofovir DF based on the percentage of participants with a decline of HBV DNA below 29 IU/mL at 48 weeks and 96 weeks.[115] Upon further data analysis through 96 weeks, higher rates of ALT normalization occurred with participants in the TAF study arm compared to those in the tenofovir DF arm. No viral resistance developed with either TAF or tenofovir DF in the studies.[114,115]

TAF was generally well tolerated by the study participants, and discontinuations from adverse events were 1% compared to 1.2% of participants in the tenofovir DF arm. The most common adverse events (incidence ≥5%) reported for TAF included headache, fatigue, abdominal pain, cough, nausea, and back pain. Similar to tenofovir DF, TAF has a safety warning of risk of lactic acidosis/severe hepatomegaly with steatosis and post-treatment severe acute exacerbations of hepatitis B, especially upon discontinuation.[114,115] There have been no reported cases of Fanconi syndrome or proximal renal tubulopathy associated with TAF. Nevertheless, renal monitoring of the serum creatinine, phosphorus,

---

creatinine clearance, urine glucose, and urine protein prior to initiating and during TAF treatment is clinically recommended. The antiviral has also been approved for HIV-1 treatment as part of a combination antiretroviral regimen with integrase strand transfer inhibitors. However, the safety and efficacy of TAF have not been established in patients with HBV and HIV coinfections. TAF is less nephrotoxic than tenofovir DF and, however, is not recommended for patients with CrCl <15 mL/minute. It is also not recommended for patients with decompensated (Child-Pugh B or C) hepatic impairment.[113–115]

Regarding the drug interaction profile of TAF, it is not recommended to be coadministered with anticonvulsants (i.e., oxcarbazepine, phenobarbital, and phenytoin), anti-tuberculosis medications (i.e., rifabutin, rifampin, and rifapentine), or Saint-John's-wort. Such coadministration will result in decreased serum levels of TAF, thus reducing its therapeutic effect. TAF is also a substrate of P-glycoprotein (P-gp) and breast cancer resistance protein (BCRP). Drugs that strongly affect P-gp and BCRP activity may lead to changes in TAF absorption.[113] Comparisons of PegIFN with the oral antivirals can be found in Table 80-7.

Combination Therapies

CASE 80-12, QUESTION 11: If C.R. fails therapy with entecavir or tenofovir DF, is combination therapy appropriate?

Combination therapy for HIV and HBV is more effective than monotherapy. The potential for additive or synergistic antiviral effects and reduced or delayed rates of viral resistance may also be possible in patients with HBV infection. Several combination therapies have been evaluated (PegIFN and lamivudine, lamivudine and adefovir, lamivudine and telbivudine), but none are superior to monotherapy.[116] Combination therapy is superior to lamivudine monotherapy in reducing the rate of resistance in patients. However, there is no such role for combination therapy for those agents (entecavir, tenofovir DF) associated with low resistance as monotherapy. Therefore, combination therapy is not appropriate for C.R. at this time.

LIVER TRANSPLANTATION

CASE 80-12, QUESTION 12: If C.R. fails therapy, continues to decompensate, and develops cirrhosis from his chronic HBV infection, what nonpharmacologic interventions are available?

Table 80-7

Comparison of HBV Treatments[85,86,96,97]

	PegIFN alfa-2a	Nucleos(t)ide Analogues
Advantages	Finite duration Lack or very little resistance Higher rates of HBeAg seroconversion within 12 months	Potent antiviral effect Well tolerated Oral ROA
Disadvantages	Moderate antiviral effect Inferior tolerability Bothersome adverse effects Subcutaneous injections	Indefinite duration Resistance risk Long-term safety unknown

PegIFN: pegylated interferon; ROA: route of administration.

One-year survival rates for patients with cholestatic or alcoholic liver disease who undergo liver transplantation are greater than 90% in most liver transplant centers.[117] Historical data for liver transplants in patients with chronic HBV infection indicated that the spontaneous risk for allograft reinfection was approximately

80%.[117–120] This reinfection rate was associated with the initial liver disease and the hepatitis B viral load at the time of transplantation, and with allograft failure, retransplantation, or death. However, with appropriate post-transplant HBV prophylactic management, overall survival rates of patients who received a liver transplant for HBV-related cirrhosis have exceeded 85% at 1 year and 75% at 5 years, making liver transplantation a viable alternative for C.R.

CASE 80-12, QUESTION 13: What are the current recommendations for prevention of recurrent HBV infection after liver transplantation?

The most efficacious approach to preventing HBV recurrence after transplantation historically was with high-dose IV HBIG given in the anhepatic and postoperative periods. Daily IV HBIG in the early postoperative period with maintenance of serum anti-HBs levels of 100 IU/L or more had an overall survival (84%) that approached that observed in other transplant recipients without HBV infection.[119,120] Furthermore, patients receiving long-term HBIG administration (>6 months) compared with patients receiving short-term HBIG (<6 months) had a lower risk for recurrent HBV infection (35% vs. 75%) and longer 3-year actuarial survival (78% vs. 48%).[119,120]

Hepatitis B Immunoglobulin Dosage, Administration, and Adverse Effects

Over the years, many liver transplant centers routinely administered immunoprophylaxis with IV HBIG 10,000 IU (10 vials, 50 mL in 250 mL of saline) given in the anhepatic (recipient liver excised) phase, then gave 10,000 IU (50 mL infused for 4–6 hours) for the next 6 days postoperatively. HBIG (10,000 IU) was generally administered on a monthly basis for life, or discontinued if HBsAg becomes positive, indicating treatment failure.[119,120] This regimen was able to achieve trough anti-HBs titers of approximately 500 IU/L and up to 2,000 IU/L, which provided protection from HBV recurrence in the majority of transplanted patients. Patients who received HBIG oftentimes experienced a serum sickness-like syndrome (fever, myalgias) and were managed by receiving premedication (i.e., acetaminophen, diphenhydramine), thus prolonging the HBIG infusion (up to 6 hours), or discontinuing HBIG therapy altogether.[119,120]

Long-term concerns associated with HBIG administration included the potential for treatment failure (HBV reinfection from extrahepatic sites despite adequate anti-HBs titers), emergence of mutant viruses, and the prohibitive high cost of therapy (>$60,000/year).[119,120] Some data suggested that pharmacokinetic modeling and use of maintenance therapy with IM administration of HBIG (e.g., 2.5–10 mL every 2–3 weeks) after a reduced induction dose (e.g., 10,000 IU anhepatically, then 2,000 IU intravenously for six doses) could achieve similar outcomes and reduce the cost associated with IV administration of the drug.[119,120]

CASE 80-12, QUESTION 14: What is the role of oral antiviral agents in liver transplant recipients with HBV?

The nucleoside and nucleotide analogs, such as lamivudine, adefovir, entecavir, tenofovir DF and, more recently, TAF, potentially prevent recurrence of HBV in patients who undergo transplants for chronic HBV infection.[120,121] Lamivudine monotherapy was proven successful in converting HBV DNA-positive patients to negative status before and after liver transplantation. Resistance in transplant and nontransplant recipients also has been observed.[120,121]

Nucleoside analogs are not FDA-approved for this prophylaxis in the United States. Several transplant centers, however, have implemented clinical protocols that administer adefovir, entecavir, or tenofovir DF before transplantation to achieve undetectable HBV DNA viral loads at the time of transplant, then combine one of these agents with HBIG in the postoperative setting.[120,121] Ultimately, these management strategies have emerged as a clinical standard in the preoperative and early postoperative period because they are effective and have low rates of resistance. Future considerations for preventing recurrent HBV infection after transplantation include combining oral nucleoside (adefovir, entecavir) with nucleotide (tenofovir DF) analogs, thus avoiding HBIG altogether.[121] At the moment, safety and efficacy data are very limited for TAF in liver transplant recipients.

HEPATITIS C VIRUS

Virology

HCV is recognized now as the most common cause of chronic NANB transfusion-associated hepatitis.[122,123] HCV is a positive-sense, single-stranded RNA virus in the Flaviviridae family that is 50 to 65 nm in diameter (see Table 80-1). It causes acute and chronic HCV infection in humans and chimpanzees. If untreated, chronic HCV can progress to cirrhosis and HCC in a subset of patients.[124] The infectious viral structure is comprised of envelope glycoproteins in a lipid bilayer that contain the viral core protein and RNA.[125] After entry into the hepatocyte, the viral RNA is translated through host machinery into a polyprotein, which is cleaved during and after translation by both host- and viral-encoded proteases into mature viral proteins and nonstructural (NS) proteins (Fig. 80-6).

Epidemiology

The worldwide prevalence estimated that up to 180 million people are infected with chronic hepatitis C. This estimate included high-risk populations, such as people who inject drugs, hemodialysis patients, cancer patients, and paid blood donors. Excluding the high-risk populations, the global prevalence of HCV infection, based on anti-HCV, was 1.6% (1.3%–2.1%) corresponding to 115 (92–149) million past viremic infections.[126–128] The estimated prevalence is conservative as it did not include high-risk populations (e.g., hemodialysis patients, cancer patients, paid blood donors, and injection drug users). The majority of these infections, 104 million, were among adults with an anti-HCV infection rate of 2.0%. There are six genotypes reported for HCV worldwide. Globally, the genotype 1 distribution is most common, accounting for 46% of all infections, followed by genotype 3 (22%), genotypes 2 and 4 (13% each). Subtype 1b accounted for 22% of all infections.[129] A further analysis of the genotype distribution across the global regions shows that genotype 1 is prevalent in Australia, Europe, Latin America, and North America (53%–71% of all cases), and genotype 3 accounting for 40% of all infections in Asia.[130–133] Genotype 4 is the most common (71%) in North America, Egypt, and the Middle East.[132]

HCV infection occurs among persons of all ages, but the highest incidence is among persons aged 20 to 39 years, with a male predominance. Blacks and whites have similar incidence rates of acute disease, whereas persons of Hispanic ethnicity have higher rates. In the general population, the highest prevalence rates of chronic HCV infection are found among persons aged 30 to 49 years and among males.[124,134,135] Unlike the racial or ethnic pattern of acute disease, blacks have a substantially higher prevalence of chronic HCV infection than do whites. In the United States, the predominant HCV genotype is type 1, with subtypes 1a and 1b accounting for 70% of cases.[134,136] Knowledge of the genotype or serotype (genotype-specific antibodies) of HCV is helpful in making recommendations and counseling regarding therapy. Once the genotype is identified, it need not to be tested again; genotypes do not change during the course of infection. Because HCV has a high mutation rate during replication, several so-called quasi-species, a heterogeneous population of HCV isolates that are closely related, may, however, exist in an infected individual.[134,136] The number of quasi-species increases during the course of infection, which allows HCV to escape the host's immune system, leading to persistent infection. In 2012, the CDC issued a new recommendation that all adults born from 1945 through 1965 (the "baby boomer" birth cohort) should undergo one-time hepatitis C testing without prior ascertainment of HCV risk status.[137] The specific cohort is selected based on data reporting HCV prevalence, disease burden, and cost-effectiveness analysis of routine screening.[138] The prevalence of anti-HCV found in this cohort is approximately 3.5%.[138,139] Furthermore, an estimated 70% of all hepatitis C-related deaths are attributed to this cohort. Birth cohort screening linked with effective hepatitis C treatment is presumed to significantly reduce future cases of decompensated cirrhosis, HCC, liver transplantation, and HCV-related deaths. The CDC screening recommendation for this cohort is also supported by the United States Preventive Services Task Force (USPSTF) and the American

Association for the Study of Liver Disease, particularly for those with high-risk behaviors, risk exposure, and medical conditions associated with HCV acquisition.[140,141]

Figure 80-6 Hepatitis C virus life cycle. (Source: Ciesek S, Manns MP. Hepatitis in 2010: the dawn of a new era in HCV therapy. Nat Rev Gastroenterol Hepatol. 2011;8(2):69–71.)

Similar to other hepatitis virus infections, acute HCV infection is defined as having an infection <6 months following acquisition of HCV. Acute HCV infection could occur whether or not the person develops clinical signs or symptoms of acute hepatitis. Six months is usually the time period to define an acute infection based on evidence that most individuals who clear HCV will do so by 6 months. Oftentimes, patients with acute HCV infection do not have a distinct symptomatic illness and most are not aware of their recent exposure to hepatitis C. If symptoms from acute infection develop, they usually develop within the first 4-12 weeks after infection and may persist between 2 and 12 weeks.[142,143] The clinical manifestations of acute HCV infection are similar to other types of viral hepatitis (e.g., jaundice, flu-like symptoms, dark urine and white stool, nausea, abdominal pain and malaise).[144] Approximately 15-20% of symptomatic acute liver disease in the United States is reported as resulting from acute HCV.[145] There are many potential sources of exposure to HCV, such as percutaneous transmission (e.g., blood transfusion, injection drug use, procedures involving potentially reused needles, tattooing, body-piercing and acupuncture) and nonpercutaneous transmission (e.g., sexual contact, high-risk sexual practices and exposure to nosocomial exposure to contaminated equipment).

PERCUTANEOUS TRANSMISSION

The incidence of HCV infection is 48% to 90% among injection drug users, and the risk of acquiring the infection in these persons is as high as 90%.[124,125,134] Of injection drug users with acute NANB hepatitis, 75% are anti-HCV positive and, unlike transfusion-related hepatitis, the incidence of HCV infection associated with injection drug use has not declined. [124,125,134] Additional risk factors for HCV infection include the presence of HBV or HIV infection. Other populations at risk for acquiring HCV include patients receiving chronic hemodialysis (up to 45%) and healthcare workers (0%–4% seroconversion after needlestick).[124,125,134]

NONPERCUTANEOUS AND SPORADIC TRANSMISSION

Nonpercutaneous transmission includes transmission between sexual partners and from mother to child. This route of transmission is less efficient compared with the percutaneous route, and is supported by data assessing sexual transmission of HCV. The risk of sexual transmission appears to be highest with male-to-male exposures, particularly with physically traumatic or rough sex.[142,143]

CASE 80-13

QUESTION 1: A 30-year-old woman presents to the clinic 3 months after having a diagnosis of chronic hepatitis C infection. Her past medical history shows that she was injecting crystal methamphetamine intermittently for 6 years, but denies using any drugs for 3 months. She is accompanied on the visit by her HCV-negative boyfriend and they ask you regarding her hepatitis C infection and her risk of transmitting hepatitis C to others. They have been together in a monogamous relationship for 2 years. What is her risk of transmitting hepatitis C to her boyfriend?

The couple do not need to alter their sexual practices. The CDC has issued recommendations regarding counseling recommendations for persons infected with hepatitis C. Patients should be counseled not to share needles or any of the injection materials, such as cookers, cottons, water, or the actual drug. The risk of HCV transmission among long-term, monogamous, discordant couples is very low. Therefore, the CDC recommends couples in that setting do not need to alter their sexual practices. The risk of HCV transmission among men who have sex with men is likely significant, especially with rough sexual activity. Household transmission of HCV can potentially occur via razors or toothbrushes, but it is not considered a risk to share food, water, or eating utensils.[141]

Compared with the high incidence of perinatal transmission of HBV from mothers to infants, perinatal transmission of HCV infection is relatively low. In general, it is considered safe for HCV-infected women to breastfeed their infants, with the exception that most experts recommend stopping breastfeeding if the mother’s nipples (or surrounding area) are cracked and bleeding. The mother can temporarily pump her breast milk (and discard it) and then resume breastfeeding after the nipple region has healed.[141] Additional concerns and areas for investigation related to mother-to-infant transmission of HCV include the timing of transmission (in utero, time of birth) and the natural history of perinatally acquired infection.

Natural History and Pathogenesis

Between 75% and 85% of persons who acquire HCV will develop chronic infection.[146] The rate of viral production is high, between 10^{10} and 10^{12} virions daily, and the lack of proofreading by the viral polymerase leads to a broad genetic diversity. Among those who develop chronic HCV infection, approximately 20% to 25% will develop cirrhosis 20 to 30 years after HCV acquisition.[147–149] As a result, the host immune system has a major challenge in its mechanisms to eradicate the virus.[150] Nevertheless, a small percentage of persons infected with HCV infection have spontaneously cleared the infection. The following host factors or characteristics that have been associated with a lower rate of chronicity include the following: younger age (<20 years old), female gender, nonblack race, competent immune status, and IL28B CC genotype.[151,152] Of note, individuals with the CC allele of IL28B genotype are more likely to spontaneously clear HCV than those with CT or TT alleles.

The pathogenesis of liver damage from HCV infection most likely results from both direct and indirect immune-mediated responses instigated by the virus. In some studies, having genotype 3a has been associated with a higher prevalence of steatosis, which is associated with fibrosis progression.[147,153,154] Hepatic fibrosis is a dynamic scarring process in which chronic inflammation stimulates production and accumulation of collagen and extracellular matrix proteins. Over time, with chronic HCV infection, the total collagen content increases and fibrosis can develop, with potential progression to cirrhosis. Fibrosis is a precursor to cirrhosis.[153,154] For persons infected with HCV infection, factors that can influence an increased rate of progression of liver fibrosis include acquisition of HCV at an older age (>40 years old), male sex, heavy alcohol use, heavy marijuana use, coinfection with HIV or HBV, and metabolic factors (e.g., steatosis and insulin resistance).[155–160] For persons who develop hepatitis C-related cirrhosis, there is an estimated 1% to 4% risk per year of developing HCC.[149,161]

Diagnosis and Screening

Two classes of assays are used in the diagnosis and management of HCV. These include serologic assays that detect specific antibody to HCV (anti-HCV) and molecular assays that detect viral nucleic acid. These assays are not used to assess the severity of disease or predict prognosis in patients infected with HCV.

Screening for additional causes and contributors of liver disease and abnormal liver function tests should be part of the diagnosis process of liver disease. There are nonviral causes of hepatic inflammation, hereditary, and acquired conditions. Secondary causes of liver disease may include alcoholic liver disease, nonalcoholic fatty liver disease (NAFLD), α-1 antitrypsin (AAT) deficiency, hemochromatosis (excessive accumulation of iron in the liver), and autoimmune hepatitis.

LABORATORY STUDIES AND SEROLOGIC ASSAYS

The laboratory studies that are commonly used to evaluate HCV infection are HCV RNA, antibodies to HCV (anti-HCV), and ALT. Persons who become infected with HCV may develop abnormal laboratory findings in the following order: detectable HCV RNA, elevation in ALT, and anti-HCV.[162–163]

CASE 80-14

QUESTION 1: N.P. is a 27-year-old, law student who presents to clinic to his routine medical evaluation. He complains to his primary care physician of having recent flu-like symptoms and nausea. He also reports noticing dark urine color and was told by his friends that he is looking “yellow and pale.” N.P. has a remote history of IV drug and alcohol use.

Recent laboratory tests reveal the following results:

ALT: 350 IU/L
Serum anti-HCV: positive
HCV RNA level: 1,100,000 IU/mL

What are the clinical and serologic features of acute HCV infection in N.P.?

N.P. clearly presents with a clinical picture consistent with acute HCV infection, including symptoms of fatigue, headache, and dark urine color. His laboratory tests show elevated ALT, positive anti-HCV, and detectable HCV RNA levels.

HCV RNA is usually detected in blood within 1 to 2 weeks after infection by a nucleic acid test (NAT). Qualitative, quantitative, and genotype test results are also performed for the HCV RNA. The period from infection until HCV RNA is detectable in plasma (by a commercially available assay) is referred to as the “eclipse phase,” or “previremic phase.” During this phase, the probability of establishment of HCV infection in susceptible hepatocytes is most likely. The eclipse phase is followed by an 8- to 10-day “ramp-up” phase in which HCV replication increases exponentially and readily becomes detectable in plasma. The “plateau phase” follows afterward with the HCV RNA viral load levels peaking 6 to 10 weeks after injection, and remains near these peak levels for approximately 40 to 60 days.[163,164] During an acute infection, detection of HCV RNA is not very reliable because RNA levels could fluctuate significantly. However, detectable HCV RNA levels are more uniform and present at the onset of symptoms.[142,165]

Between 4 and 12 weeks after infection, patients may have liver cell injury resulting in an elevation in serum ALT levels. Increases in ALT occur 1 to 2 weeks after detectable HCV RNA levels are present, and precede the development of anti-HCV. Usually, after an acute infection, the mean ALT could increase to 800 IU/L range. The CDC uses an ALT >200 IU/L during the period of acute illness as part of the diagnostic criteria.[162]

The last of the three abnormal laboratory findings associated with HCV infection is the presence of antibodies to HCV in the blood. Anti-HCV is usually detectable between 8 and 12 weeks after infection. Approximately after 12 weeks, >90% of patients will have positive anti-HCV. This is referred to as the "serologic window period," which describes the time period from initial infection until seroconversion.[143] Having detectable anti-HCV does not clearly differentiate acute from chronic HCV infection. Moreover, anti-HCV is not a reliable marker to diagnose acute HCV because only approximately 50% to 70% of patients have detectable anti-HCV at the onset of symptoms.[164,165]

CASE 80-14, QUESTION 2: After N.P. or any other person becomes infected with HCV, what is the typical sequence of laboratory findings?

Detectable HCV RNA, then increased aminotransferase levels, then anti-HCV positive.

The gold standard for the laboratory diagnosis of acute HCV infection is anti-HCV seroconversion (negative anti-HCV before suspected exposure and positive anti-HCV following exposure) combined with a positive HCV RNA viral load test.[145,164] However, because no many patients are unaware of their exposure or risk of infection, they may not present to their healthcare providers early enough to be evaluated and diagnosed. Oftentimes, acute HCV is diagnosed based on the first-time detection of HCV RNA and newly elevated ALT compared to negative laboratory results at baseline. Close follow-up of patients who have encountered high-risk exposures is recommended to establish the diagnosis and their treatment care. The laboratory testing for a known exposure to HCV is recommended as follows[162,166]:

- At initial presentation: anti-HCV, HCV RNA and ALT
- At 4 weeks from time of suspected exposure: anti-HCV, HCV RNA, and ALT
- At 12 weeks from time of suspected exposure: anti-HCV, HCV RNA, and ALT

CASE 80-14, QUESTION 3: According to the CDC 2016 case definition of acute hepatitis C, what level of increased ALT is required as part of the clinical description?

An ALT >200 IU/L. N.P.'s ALT result is 350 IU/L.

Acute HCV infection rarely causes a life-threatening illness. The CDC 2016 case definition for acute hepatitis C includes clinical and laboratory criteria, case classification as probable or confirmed, and criteria to distinguish a new case from an existing case.[162] Clinical criteria of acute hepatitis C is described as an illness with an onset of any sign or symptom consistent with acute viral hepatitis (e.g., fever, headache, abdominal pain, malaise, anorexia, nausea, vomiting, and diarrhea) combined with jaundice, or a peak-elevated serum ALT level >200 units/L during the acute illness phase.[162,165,166]

As part of the comprehensive patient work-up, a complete laboratory evaluation of the patient with chronic HCV infection includes the following[152,165,167]:

- General: CBC, platelet count, serum creatinine, and thyroid function tests (TSH). Because some studies have shown that persons with vitamin D deficiency have reduced response to hepatitis C treatment, some experts recommend obtaining baseline vitamin D levels (1,25-OH vitamin D).

- Hepatic inflammation and function: ALT or aspartate aminotransferase (AST), tota and direct bilirubin, alkaline phosphatase, serum albumin, INR.
- Assays to detect coinfections: hepatitis A antibody, hepatitis B surface antigen, hepatitis B core antibody, hepatitis B surface antibody, HIV antibody.
- HCV RNA level (viral load): a quantitative HCV RNA viral load to confirm that the patient has chronic HCV infection, and to establish a pretreatment baseline level. In the absence of treatment, it is not necessary to repeatedly assess the HCV RNA levels because monitoring values over time does not provide useful prognostic information.
- HCV genotype: HCV exists as one of six distinct genotypes with significantly different clinical characteristics, mostly with respect to treatment response rates. In the United States, HCV genotype 1 is the most common, accounting for between 70% and 74% of prevalent cases. Knowing the HCV genotype is very important because response to antiviral therapy is very different among different genotypes and treatment protocols differ substantially.
- IL-28B testing: This is a single-nucleotide polymorphism (SNP) at the IL-28B loc that codes for interferon lambda and strongly correlates with HCV treatment response, especially with interferon-based therapies. Since the emergence and successful cure rates, or sustained virologic response (SVR) with the direct-acting antiviral (DAA) drugs, interferon-based therapies are no longer recommended for chronic HCV treatment. This test is now optional.

Serologic assays in terms of noninvasive, serum markers have clinical utility in predicting the presence or absence of significant fibrosis or cirrhosis and, however, are not useful in differentiating between intermediate stages of fibrosis. The indirect markers include the aspartate aminotransferase-to-platelet ratio index (APRI), FIB-4, FibroIndex, Forns Index, HepaScore (FibroScore), FibroSure, and FibroTest-ActiTest.

The APRI model is an easily calculated method to predict significant, severe fibrosis or cirrhosis. It is calculated using the patient's aspartate aminotransferase (AST) level and platelet count, and the upper limit of normal of AST level. A meta-analysis of 40 studies found that an APRI cut-off of greater than or equal to 0.7 had an estimated sensitivity (77%) and specificity (72%) for detection of significant hepatic fibrosis (greater than or equal to F2 by METAVIR). A cut-off score of a least 1.0 has an estimated sensitivity (61%–76%) and specificity (64%–72%) for detection of severe fibrosis/cirrhosis (F3–F4 by METAVIR). For detection of cirrhosis, a cut-off score of at least 2.0 was more specific (91%), but less sensitive (46%).[168–171] APRI has good diagnostic utility for predicting severe fibrosis or cirrhosis, but does not accurately differentiate intermediate fibrosis from mild or severe fibrosis. The liver guidelines recommend using APRI with other noninvasive markers of fibrosis.

The FIB-4 is a simple, quick, and inexpensive test that provides results immediately. The result is generated using age, AST, ALT, and platelet count. A cut-off value of less than 1.45 has a sensitivity (74%) and specificity (80%) in excluding significant fibrosis. A cut-off value >3.25 has a specificity (98%) in confirming cirrhosis. FIB-4 has valid utility in excluding or confirming cirrhosis; however, values between 1.45 and 3.25 do not clearly discriminate fibrosis.[172] Thus, additional methods to predict liver fibrosis are recommended.

The FibroIndex is a simple scoring method comprised of three biochemical markers: AST, platelet count, and gamma globulin. A cut-off value ≤ 1.25 has a sensitivity (40%) and specificity (94%) for mild fibrosis (F0 or F1 by METAVIR). In contrast, a cut-off value ≥ 2.25 has a sensitivity (36%) and specificity (97%) for significant fibrosis (F2 or F3 by METAVIR). Patients with F4 fibrosis were not included in the study.[173]

The Forns Index uses a complicated calculation method. It incorporates parameters, such as age, gamma glutamyltransferase (GGT), cholesterol, and platelet count. A cut-off value of <4.25 has a negative predictive value of 96% for excluding significant fibrosis (F2, F3, or F4). On the other hand, a cut-off of >6.9 has a positive predictive value of 66% for significant fibrosis (F2, F3, or F4). The Forns Index is useful and has good predictive value in selecting those with low risk of significant fibrosis, but does not reliably predict more advanced fibrosis or cirrhosis.[174] Patients with genotype 3 HCV infection may have varying cholesterol levels; thus, the Forns Index should not be used in these patients.

The HepaScore or FibroScore algorithm is more complex than other indirect markers. Additional fibrosis markers (i.e., age, sex, total bilirubin, GGT, α-2-macroglobulin, and hyaluronic acid levels) are included in the equation. Cut-off value ≤0.2 has a negative predictive value of 98% to exclude fibrosis. In contrast, cut-off value ≥0.8 has a positive predictive value of 62% for predicting cirrhosis.[175] The HepaScore has good utility at excluding significant fibrosis, but not as good at predicting cirrhosis.

The FibroSure and FibroTest-ActiTest are identical tests marketed in the United States and Europe. FibroSure is the test available in the United States. These tests are utilized to assess liver inflammation and fibrosis. The FibroSure provides estimates of grade and stage of fibrosis. It includes patient age and gender along with a composite of six biochemical markers associated with hepatic fibrosis: α-2-macroglobulin, haptoglobulin, GGT, apolipoprotein A1, total bilirubin, and ALT. The cut-off value <0.31 has a negative predictive value of 91% for the absence of clinical significant fibrosis. The positive predictive value for presence of significant fibrosis at a cut-off value >0.48 was 61% and cut-off of 0.72 was 76%.[176] There are contraindications to using the FibroSure test (e.g., Gilbert disease, acute hemolysis, extrahepatic cholestasis, post-transplantation, or renal insufficiency), which may result in inaccurate quantitative calculations and predictions.

Aside from the invasive, indirect markers for predicting liver fibrosis or cirrhosis, there are direct markers of fibrosis. Direct markers of fibrosis include procollagen type (II, III, IV), matrix metalloproteinases, cytokines, and chemokines. These markers exhibit variable effectiveness in predicting liver fibrosis. The FIBROSpect II is the only commercially available test that combines hyaluronic acid, tissue inhibitor of a metalloproteinase-1 (TIMP-1), and α-1-macroglobulin to predict fibrosis stages (F2–F4). An index score of >0.42 indicates the presence of stage F2 to F4 fibrosis. The cut-off values for sensitivity and specificity are 80.6% and 71.4%, respectively.[176,177] The FIBROSpect II test is a good tool to use to determine the presence of absence of cirrhosis in patients who have contraindications to liver biopsy, or those who refuse it. These markers may serve as reliable clinical alternatives in patients who are not candidates for liver biopsy. If noninvasive methods provide a clear assessment of hepatic fibrosis, then a liver biopsy may not be needed or warranted.

Radiologic imaging of the liver has been effective noninvasive, diagnostic techniques for identifying cirrhosis and stratifying the stages of liver fibrosis. Several techniques that are currently been used include hepatic ultrasound, transient ultrasound elastography, and magnetic resonance elastography.

BIOPSY

Liver biopsy with histologic analysis continues to be the gold standard for diagnosing other causes of liver disease and establishing severity of fibrosis. It provides information on both the grade (degree of inflammation associated with ongoing liver disease injury) and the stage (amount of currently established fibrosis). Some factors (e.g., alcohol consumption, increased hepatic iron concentration, and steatosis) are associated with accelerated fibrosis progression and may elicit concern for advanced fibrosis.[178–180] Some limitations of a liver biopsy include its invasive technique, associated risks of bleeding and complications, and the probability of incorrectly staging fibrosis in about 20% of patients.[178–180] Because of these limitations and the development of noninvasive tests that estimate hepatic fibrosis, liver biopsy is now used less frequently.

IMMUNOCOMPROMISED PATIENTS

Kidney transplant recipients also have a high incidence of HCV infection (6%–28%), which may be acquired through dialysis before transplant or from the allograft or blood products after transplantation.[181,182] After kidney transplantation, elevation in aminotransferases is more common in anti-HCV-positive compared with anti-HCV-negative patients (48% and 14%, respectively), and cirrhosis has been reported with the former.[181,182]

Clinical and Extrahepatic Manifestations

Most patients with acute HCV infection are asymptomatic.[126,134,135] In contrast, approximately 40% of patients with chronic HCV infection will develop at least one extrahepatic manifestation. Specific extrahepatic conditions may vary, and their prevalence is estimates derived from observational studies. Extrahepatic manifestations and conditions include cryoglobulinemic vasculitis, renal disorders with or without cryoglobulinemia, dermatologic manifestations including cutaneous leukocytoclastic vasculitis and porphyria cutanea tarda, diabetes mellitus and metabolic syndrome, and lymphomas.[183–190] Successful eradication of HCV may reduce the risk of some extrahepatic manifestations (i.e., lymphoma and diabetes) and conditions (i.e., cryoglobulinemic vasculitis and renal disease).

Prevention of Hepatitis C

PRE-EXPOSURE PROPHYLAXIS

No vaccines are effective against HCV, and current measures to prevent hepatitis C infection have largely focused on identifying high-risk uninfected persons and counseling them on risk-reducing strategies to prevent infection. The CDC and the National Institutes of Health have published recommendations that address these issues.[126,162] Suggested primary preventive measures are that in healthcare settings, adherence to universal (standard) precautions for the protection of medical personnel and patients be implemented and that HCV-positive individuals should refrain from donating blood, organs, tissues, or semen. In some situations, the use of organs and tissues from HCV-positive individuals may be considered. For example, in emergency situations, the use of a donor organ in which the HCV status is either positive or unknown may be considered in an HCV-negative recipient after full disclosure and informed consent. Strategies should be developed to identify prospective blood donors with any history of injection drug use. Such individuals must be deterred from donating blood.

Furthermore, safer sexual practices, including the use of latex condoms, should be strongly encouraged in persons with multiple sexual partners. In monogamous long-term relationships, transmission is rare.[126–128] Although HCV-positive individuals and their partners should be informed of the potential for transmission, insufficient data exist to recommend changes in current sexual practice in persons with a steady partner. It is recommended that sexual partners of infected patients should be tested for antibody to HCV.

In households with an HCV-positive member, sharing razors and toothbrushes should be avoided.[126–128] Covering open wounds is recommended. Injection needles should be carefully disposed of using universal precaution techniques. It is not necessary to avoid close contact with family members or to avoid sharing meals or utensils. No evidence justifies exclusion of HCV-positive children or adults from participation in social, educational, and employment activities.

Additionally, pregnancy is not contraindicated in HCV-infected individuals. Perinatal transmission from mother to baby occurs in less than 6% of instances.[126–128] No evidence indicates that breast-feeding transmits HCV from mother to baby; therefore, it is considered safe. Babies born to HCV-positive mothers should be tested for anti-HCV at 1 year.

Finally, needle exchange and other safer injection drug-use programs may be beneficial in reducing parenterally transmitted diseases.[126–128] Expansion of such programs should be considered in an effort to reduce the rate of transmission of hepatitis C. It is important that clear and evidence-based information be provided to both patients and physicians regarding the natural history, means of prevention, management, and therapy of hepatitis C.

GOALS OF THERAPY

CASE 80-15

QUESTION 1: K.C., a 20-year-old woman, presents to clinic for evaluation of liver enzyme elevation. She recently saw her gynecologist and labs revealed marked ALT/AST increase. She denies any recent symptoms or change in health other than flu-like illness a few months ago. She currently works as a waitress at Denny's. She denies prior medical problems and taking any prescribed medications and herbal/OTC medications. K.C. reports that she has been using IV heroin since she was 15 at the mall and that her best friend just died of an overdose. She went on a binge after he died and was not careful about needle sharing. She previously tested (about a year ago) for HCV and HIV by her physician. The laboratory results were both negative.

Upon physical examination, she has multiple tattoos and body piercings, as well as a few track marks on arms. Her physical examination is otherwise unremarkable. Liver is not enlarged, and there are no asterixis (no stigmata of liver disease), ascites, nor jaundice. Abdominal ultrasound is normal.

ALT: 45 units/L
AST: 64 units/L
Serum anti-HCV: positive
HCV RNA level: 6.1 million IU/mL

HCV genotype 1a
FibroSure: F1 (mild form of fibrosis; no cirrhosis)

K.C. and her parents decide they want her to be treated. They agree to continue support. K.C. agrees to go to Narcotics Anonymous and see psychological counseling. What is the goal of therapy for K.C. and the definition of a sustained virologic response 12 (SVR12)?

K.C. clearly has a clinical picture consistent with chronic HCV infection, including symptoms of flu-like symptoms, an elevated ALT, positive anti-HCV, and detectable HCV RNA levels. A SVR12 is defined as the HCV RNA level remaining undetectable for 12 weeks after completing therapy. The primary goal of HCV therapy is achieving virologic cure, or a SVR24 which is defined as the HCV RNA level remaining undetectable 24 weeks after completion of therapy. A negative HCV RNA level is <25 IU/mL, below the level of detection by sensitive test assays.

The primary goal of HCV therapy is to achieve SVR, which is an undetectable HCV RNA level using a sensitive assay (<25 IU/mL)

---

12 weeks after completion of therapy for hepatitis C.[126] This is referred to as a SVR12. Among persons who achieve a SVR12, more than 99% proceed to achieve SVR24.[191] A long-term follow-up of patients who achieve a SVR24 has demonstrated nearly 100% remain HCV RNA-negative years after therapy.[192–194] In clinical terms, achieving SVR24 is comparable to achieving virologic cure or total eradication of the HCV.

The impact of a SVR is remarkably positive because patients have an improvement in liver inflammation and fibrosis compared to those who do not achieve a SVR. Study data from pooled analysis of paired liver biopsies before and 1 month to 6 years after treatment with standard interferon monotherapy, PegIFN monotherapy, or PegIFN with ribavirin showed those patients who had a SVR were twice likely to have lower necroinflammatory scores after treatment versus patients who relapsed (67% vs. 32%).[195] Other studies have also confirmed the long-term histologic benefit.[192–194,196] In a study involving the general population, patients with advanced fibrosis who underwent antiviral therapy and achieved a SVR had reduction in overall mortality, liver-related death, liver failure, and HCC when compared with those who did not achieve a SVR.[197] Most of this survival benefit from successful treatment response was associated with improved clinical outcomes, primarily because of lower rates of liver failure. In a meta-analysis of 35 studies, investigators showed a clear benefit in the 5-year overall survival with HCV treatment, including patients with cirrhosis and with HIV coinfection.[198] With regard to the extrahepatic manifestations, successful treatment of HCV is associated with improvement or remission of insulin resistance and diabetes mellitus.[199,200] Overall, an SVR is associated with reversal of hepatic inflammation and fibrosis, and can reduce the chance of dying from hepatitis C by at least 60%.[201]

FACTORS THAT PREDICT RESPONSE TO THERAPY

CASE 80-15, QUESTION 2: K.C.'s parents have read about HCV infection and how treatment response may be affected by the person's genotype. They ask you if K.C.'s genotype could affect her successful response to HCV therapy?

In the DAA therapy era, K.C.'s genotype should not really affect her response to treatment. Treatment responses are high across all genotypes if a DAA-based combination appropriate for the genotype is used. There are viral and host factors that predict a person's response to therapy, such as the HCV genotype, HCV RNA level, IL28B genotype, race, age, gender, and degree of hepatic fibrosis. The HCV has six major genotypes, numbered 1 through 6. During the interferon era of treatment and prior to the emergence of the potent DAA drugs, the genotype was the predictor of obtaining an SVR.[202–204] In contrast, the role of HCV genotype in predicting treatment response has lessened in its influence as the DAAs are highly efficacious in their treatment of all genotypes.

The HCV RNA level had an influence in the successful treatment outcome in the interferon era. Patients with high RNA levels and genotype 1 infection had approximately 27% lower chance of achieving a SVR.[205] In the current DAA era, however, the baseline HCV RNA has little impact on achieving a SVR. Of note, in a post hoc analysis, a very high baseline RNA level of >6 million IU/mL is associated with reduced likelihood of SVR with shorter duration (8 weeks) of therapy with ledipasvir–sofosbuvir.[206]

The polymorphisms in the IL28B gene is associated with a difference in treatment response rates for persons receiving interferon-based therapies. The CT or TT alleles were associated with a 40% lower SVR rate compared to patients with the CC allele.[207] The majority of African-Americans have either the less favorable genotypes (CT or TT). On the other hand, Asians have the highest proportion of the CC genotype that may lead to better response to interferon-based therapy. In the DAA era, IL28B genotype does not seem to influence treatment response. Similarly, in the DAA era, a person's race, age, and gender do not appear to have a significant influence on treatment response for HCV infection.

The degree of hepatic fibrosis may still influence the SVR rates for persons receiving DAA therapies. Advanced fibrosis, defined as F3 (precirrhosis or bridging fibrosis), and F4 (cirrhosis) were associated with a much lower virologic cure rate across all genotypes (between 10% and 20% lower) during the interferon era.[202–204] This is similarly observed in patients receiving DAA therapies. Patients with decompensated cirrhosis (Child-Pugh class B or C) had lower SVR rates (86%–87%) with 12-week treatment of ledipasvir/sofosbuvir compared with SVR rates of >95% in similarly treated noncirrhotic patients.[208] Current strategies to improve the SVR rates for patients with cirrhosis include adding ribavirin to the DAA combination therapies and lengthening the duration of therapy.

CURRENT TREATMENT STRATEGIES OF CHRONIC HEPATITIS C

Historically, genotype 1 hepatitis C was considered the most difficult to treat hepatitis C genotype. From 1998 to 2013, therapy evolved from interferon monotherapy, to PegIFN monotherapy, to PegIFN plus ribavirin, to triple therapy with PegIFN plus ribavirin plus an NS3/4A protease inhibitor (boceprevir or telaprevir), the first-generation DAA serine protease inhibitors. Research methodologies for enhancing the effectiveness of HCV treatments and improving virologic cure rates, or SVR, primarily focused on genotype 1. The most promising of these explorations has been the development of the DAA agents. These oral compounds are developed to directly target the specific steps within the viral replication genome of hepatitis C. In late 2013 and most of 2014, the standard of care (SOC) for initial therapy of genotype 1 comprised of PegIFN plus ribavirin plus either sofosbuvir or simeprevir. Since 2015, the SOC for genotype 1 including the rest of the six genotypes consists of all-oral, interferon-free therapy with DAA combination regimens because of their significant high SVR rates and better tolerability profile. With the SOC changed from PegIFN to the DAAs, the treatment duration was also shortened from the traditional 48 weeks to 24 and then to 12 weeks. These oral compounds are developed to directly target the specific steps within the viral replication genome of hepatitis C. The four classes of DAAs are defined by their mechanism of action and therapeutic target, such as the NS proteins 3/4A (NS3/4A) serine protease inhibitors, NS5B nucleoside polymerase inhibitors, NS5B non-nucleoside polymerase inhibitors, and NS5A inhibitors.[209]

According to the AASLD/IDSA HCV guidance, treatment should be offered to all persons with chronic HCV infection because the DAAs are safer, better tolerated, and more effective in achieving virologic cure.[210] There are absolute contraindications for DAA treatment: persons with short life expectancies (<12 months); the use of ribavirin in pregnant women, women who may become pregnant, or men whose female partners are pregnant.[211,212] Persons with chronic HCV infection who are of reproductive age and are to receive treatment that includes ribavirin should be strongly advised to use two forms of contraception during treatment and for at least 6 months following the end of treatment. Similarly, there are relative contraindications to considerations for initiating HCV treatment. They include active severe substance abuse, psychiatric issues not controlled or stabilized, and social issues that may negatively affect a person’s adherence to treatment, laboratory, and scheduled office visits.

Direct-Acting Antivirals

CASE 80-15, QUESTION 3: Genotyping of K.C.'s HCV infection shows that she has genotype 1a. What pharmacologic agents are effective treatments for patients with chronic HCV infection genotype 1a?

K.C. has a lot of treatment options with the DAA combination therapies. She has no signs of cirrhosis, or decompensated disease with splenomegaly, ascites, coagulopathy, and esophageal varices. Furthermore, she does not have HIV or HBV coinfections that could accelerate the progression of hepatitis C. The DAA combination therapies are highly potent and successful in achieving >90% SVR rates for persons with genotype 1 (1a and 1b) HCV infection (Table 80-8).

NS3/4A Protease Inhibitors

The NS3/4A protease inhibitors function through two mechanisms. They block the NS3/4A serine protease, an enzyme involved in post-translational processing and replication of HCV. They disrupt the virus replication process by blocking the NS3 catalytic site or the NS3/NS4A interaction.[213] The NS3/NS4A protease inhibitors also block the TRIF-mediated Toll-like receptor signaling and Cardif-mediated retinoic acid-inducible gene 1 (RIG-1) signaling, which result in impaired induction of interferons and blocking viral elimination (see Table 80-8).

Telaprevir and **boceprevir** were the first-generation NS3/4A protease inhibitors for HCV treatment. They were used in combination with PegIFN-α2a plus ribavirin for the treatment of genotype 1 infection. The clinical importance of telaprevir and boceprevir substantially diminished because of their cumbersome administration, substantial adverse effects, drug–drug interactions, and low barrier to resistance. As more-potent and better-tolerated protease inhibitors were developed and approved for HCV treatment without PegIFN-α2a and ribavirin, telaprevir and boceprevir eventually became clinically obsolete. The newer protease inhibitors have fewer drug–drug interactions, improved dosing schedules, and fewer severe adverse effects. In spite of their improved efficacy against genotype 1 infection, the newer protease inhibitors have limited efficacy against other genotypes and lower barrier to resistance.[214] The subsequent-generation protease inhibitors available in the United States include simeprevir, grazoprevir, and paritaprevir. Asunaprevir is available in Japan.

Simeprevir is the first second-generation, macrocyclic protease inhibitor. It is approved as 150-mg capsule for the use in combination with PegIFN-α2a plus ribavirin, or in combination with sofosbuvir with or without ribavirin for chronic HCV genotype 1 infection.[215] Simeprevir is administered orally once daily with food and should not be used as monotherapy. No dose adjustment is required in patients with renal impairment. Simeprevir cannot be used in patients with moderate (Child-Pugh class B) or severe (Child-Pugh class C) hepatic impairment because of two- to fivefold increases in drug exposure. Higher simeprevir exposure was reported in patients of East Asian ancestry; thus, simeprevir should be used with caution for this patient population.[216]

Table 80-8

Comparison of Direct-Acting Antiviral Agents for HCV Treatment[243]

	Protease Inhibitors	NS5B Polymerase Inhibitors	NNPI	NS5A Inhibitors
DAA agents	Grazoprevir Paritaprevir Simeprevir	Sofosbuvir	Dasabuvir	Daclatasvir Elbasvir Ledipasvir Ombitasvir Velpatasvir
MOA	Block the function of the NS3/NS4A serine protease	Block the function of the NS5B polymerase	Block the function of the NS5B polymerase	Block the replication complex and regulation
Activity against genotype	Grazoprevir: 1,4,6[a] Paritaprevir: 1 Simeprevir: 1	1–4	1	Daclatasvir:1–3 Elbasvir: 1,4,6[a] Ledipasvir: 1,4,5,6 Ombitasvir: 1 Velpatasvir: 1–6
Potency	High (varies by GT)	Moderate-to-high (consistent across GTs)	Varies by GT	High (against multiple GTs)
Barrier to resistance	Low (GT 1a < GT 1b)	High (1a = 1b)	Very low (1a < 1b)	Low (1a < 1b)
Potential for drug interactions	High	Low	Variable	Low-to-moderate
Adverse effects	Rash, anemia, bilirubin increase	Mitochondrial toxicity; drug interactions with HIV drugs (NRTIs) and RBV	Variable	Variable
Dosing	Daily to 3 times daily	Daily to 2 times daily	Daily to 3 times daily	Daily
Comments	Future-generation PIs will have pangenotypic activity and will have higher barriers to resistance	Single target for binding at the active site of viral replication	Many targets for binding at allosteric sites	Multiple antiviral MOA

MOA, mechanism of action; NS5B, nonstructural protein 5B; NNPIs, non-nucleoside polymerase inhibitors; NS5A, nonstructural protein 5A; GT, genotype; HIV, human immunodeficiency virus; NRTIs, nucleos(t)ide RT inhibitors; RBV, ribavirin.

[a] Elbasvir/grazoprevir has activity against HCV genotype 6, but not FDA-approved for treating this genotype.

Simeprevir is overall well tolerated although pruritus and nausea have been reported. In clinical trials, treatment discontinuations from adverse effects were uncommon.[217,218] However, photosensitivity and rash have occurred that led to serious reactions requiring hospitalization for some patients in the trials. Patients taking simeprevir should be cautioned about the risk of photosensitivity and rash, and to use sun-protective measures and/or limit sun exposure while on treatment. If a severe rash or photosensitivity reaction occurs, simeprevir should be discontinued. Transient, mild elevations in bilirubin have been reported, which may result from decreased bilirubin elimination related to inhibition of the hepatic transporters OATP1B1 and MRP2. This does not suggest worsening of hepatic function.

With regard to drug interactions, simeprevir is oxidatively metabolized by CYP3A isoenzyme, primarily the hepatic and intestinal CYP3A4.[219] Coadministration with potent inducers and inhibitors of CYP3A4 will affect the serum levels of simeprevir. It is observed to inhibit the OATP1B1/3 transporter; therefore, serum levels of substrates of OATP1B1/3 (atorvastatin and rosuvastatin) could increase.[215]

The efficacy of simeprevir is affected by the presence of resistance mutations or polymorphisms of the NS3/4A protease. In particular, the presence of Q80K polymorphism was associated with a lower SVR rate (58% vs. 84% if the Q80K was not present).[216] However, data suggest that the Q80K mutation does not significantly affect SVR rates when simeprevir is coadministered with sofosbuvir, an NS5B polymerase inhibitor.[220] The emergence of other resistance mutations during unsuccessful treatment with either telaprevir or boceprevir, such as R155K and A156T/V, has been reported to affect the clinical response to simeprevir.[215]

Grazoprevir is a potent, second-generation protease inhibitor that is only available in combination with an NS5A inhibitor, elbasvir. Grazoprevir has activity against HCV genotypes 1, 4, and 6 and, however, is only FDA-approved for genotypes 1 and 4. (See elbasvir/grazoprevir section.)

Paritaprevir is the third, second-generation protease inhibitor FDA-approved for the treatment of HCV genotype 1 infection. It is coadministered with low-dose ritonavir, an HIV protease inhibitor, for pharmacokinetic enhancing effects via inhibition of CYP3A-mediated metabolism. Ritonavir does not have any anti-HCV activity. Paritaprevir and ritonavir are coformulated as a fixed-dose combination with ombitasvir, an NS5A inhibitor. (See paritaprevir/ritonavir/ombitasvir/dasabuvir section.)

NS5A Inhibitors

The NS5A inhibitors block the protein that has a role in viral replication and the assembly of the HCV (see Table 80-8).[221–222] The NS5A class is relatively potent and effective across all genotypes; however, it has a low barrier to resistance and variable toxicity profile. When coadministered with PegIFN and ribavirin, NS5A inhibitors can substantially reduce HCV RNA levels and improve SVR.[223] Available NS5A inhibitors in fixed-dose combinations with other DAAs comprise of ledipasvir, ombitasvir, and elbasvir. Daclatasvir is the only available, stand-alone NS5A inhibitor.

Daclatasvir (Daklinza) is a NS5A inhibitor mainly used in combination with sofosbuvir, a NS5B polymerase inhibitor. It has activity against HCV genotypes 1, 2, and 3. It is dosed as 60 mg orally once daily with or without food. It cannot be used as monotherapy and approved to be coadministered with sofosbuvir with or without ribavirin. If sofosbuvir is discontinued, daclatasvir should also be discontinued. Dose adjustments for patients with renal or hepatic impairment are not required. Daclatasvir is well tolerated with commonly reported adverse effects of headache, fatigue, and nausea from clinical trial data.[224,225]

Daclatasvir is metabolized via the CYP3A pathway and should not be coadministered with potent inducers, such as rifampin, phenytoin, carbamazepine, and Saint-John's-wort. The serum levels of daclatasvir will be significantly reduced to suboptimal efficacy. When coadministered with moderate CYP3A inducers (e.g., efavirenz, etravirine, dexamethasone, and nafcillin), the dose of daclatasvir should be increased to 90 mg once daily. On the other hand, when given with potent CYP3A inhibitors (e.g., HIV protease inhibitors, some azole agents, and clarithromycin), the dose of daclatasvir should be reduced to 30 mg once daily. Aside from the CYP450 system, daclatasvir also inhibits P-glycoprotein (P-gp), organic anion transporting polypeptide (OATP) 1B1 and 1B3, and the BCRP. Digoxin dose may need to be adjusted when coadministered with daclatasvir.

In vitro resistance mutations associated with daclatasvir include polymorphisms at M28, A30, L31, and Y93, which is the most clinically relevant. Based on the clinical trial data, the emergence of Y93H polymorphism was associated with lower SVR rates and responsible for several virologic failures.[225]

Elbasvir is a NS5A inhibitor only available as a fixed-dose combination with grazoprevir, a NS3/4A serine protease inhibitor. (See elbasvir/grazoprevir section.)

Ledipasvir is a NS5A inhibitor only available as a fixed-dose combination with sofosbuvir, a NS5B polymerase inhibitor. (See ledipasvir/sofosbuvir section.)

Ombitasvir is a NS5A inhibitor only available as a fixed-dose combination with the protease inhibitors paritaprevir and ritonavir, and administered in combination with dasabuvir, a NS5B non-nucleotide inhibitor. (See paritaprevir/ritonavir/ombitasvir with or without dasabuvir section.)

Velpatasvir is a NS5A inhibitor that has pangenotypic antiviral activity against genotypes 1 to 6. It is only available as a fixed-dose combination with sofosbuvir, a NS5B polymerase inhibitor. (See sofosbuvir/velpatasvir section.)

NS5B RNA-Dependent RNA Polymerase Inhibitors

NS5B is an RNA-dependent RNA polymerase involved in post-translational processing that is necessary for replication of HCV. The polymerase has a catalytic site for nucleoside binding and four other sites for non-nucleoside binding to cause an allosteric alteration. The enzyme structure is highly conserved across all six genotypes. Two classes of NS5B polymerase inhibitors include the nucleoside/nucleotide analogues (NPIs) and non-nucleoside analogues (NNPIs). The NPIs bind to the catalytic site of NS5B, whereas NNPIs function as allosteric inhibitors.[213,214]

Sofosbuvir (Sovaldi) is the first NS5B NPI available for HCV treatment. It should not be used as monotherapy and most effective when used in many combinations with other antivirals to treat different genotypes. Sofosbuvir is available as a 400-mg tablet and given orally once daily with or without food. It is primarily renally eliminated, however, pharmacokinetic studies suggest no dose adjustments are required for patients with mild or moderate renal impairment (eGFR >30 mL/minute/1.73 m^2).[226] Nevertheless, serum levels of sofosbuvir are increased in patients with severe renal impairment and receiving hemodialysis. There is insufficient data for dose-adjustment recommendations in these patients. Sofosbuvir can be given in patients with moderate (Child-Pugh class B) or severe (Child-Pugh class C) hepatic impairment and cirrhosis without dose adjustments.

Sofosbuvir is generally well tolerated. When given with PegIFN and ribavirin, the commonly reported adverse effects of sofosbuvir and ribavirin (with or without PegIFN) were fatigue, headache, nausea, insomnia, and anemia.[227,228] Concomitant use of sofosbuvir and sofosbuvir-containing regimens with amiodarone is contraindicated due to episodes of severe bradycardia and fatal cardiac arrest.[229,230]

As a substrate of the P-gp drug transporter, sofosbuvir has significant drug interactions with potent intestinal P-gp inducers

that could decrease its serum levels. The coadministration of sofosbuvir with the anticonvulsants (e.g., carbamazepine, phenytoin, phenobarbital, oxcarbazepine), anti-tuberculosis drugs (e.g., rifampin, rifabutin, rifapentine), and Saint-John's-wort is contraindicated. Of note, the coadministration of sofosbuvir and amiodarone is also contraindicated.[229,230] In vitro resistance polymorphisms have been reported for sofosbuvir; however, their clinical significance is unclear.

Dasabuvir, unlike sofosbuvir, is a NS5B NNPI that is administered and packaged with paritaprevir/ritonavir/ombitasvir. (See paritaprevir/ritonavir/ombitasvir with or without dasabuvir section.) As a class, the NNPI class is less potent than the NPI class, is more specific for genotype 1, has a low-to-moderate barrier to resistance and a variable toxicity profile.[231]

CASE 80-15, QUESTION 4: According to the 2016 AASLD Guidelines, what fixed-dose DAA combination therapies could K.C. benefit from and for what duration length of treatment?

There are currently four FDA-approved fixed-dose combinations that are effective against HCV genotype 1 (and other genotypes). K.C. could benefit from either of the following:

a. elbasvir 50 mg/grazoprevir 100 mg (Zepatier) 1 tablet orally once daily for 12 weeks;

b. ledipasvir 90 mg/sofosbuvir 400 mg (Harvoni) 1 tablet orally once daily for 12 weeks;

c. sofosbuvir 400 mg/velpatasvir 100 mg (Epclusa) 1 tablet orally once daily for 12 weeks; and

d. paritaprevir 50 mg/ritonavir 33.33 mg/ombitasvir 8.33 mg plus dasabuvir 200 mg (PrOD; Viekira XR) 3 tablets orally once daily with food plus ribavirin (weight-based dosing) given in two divided doses for 12 weeks.

Fixed-Dose Combinations

Elbasvir/Grazoprevir

As a coformulated single tablet, elbasvir 50 mg plus grazoprevir 100 mg (Zepatier) is administered orally once daily for either 12 or 16 weeks.[232] This regimen is administered with or without weight-based ribavirin, depending on certain patient characteristics. Elbasvir/grazoprevir has been studied and approved for treatment of HCV and HIV coinfection. Patients should have documentation of baseline aminotransferases and be tested for current or previous HBV infection (HBsAg and anti-HBc) to ensure that there is no risk of HBV flares during HCV treatment. The regimen is the first of the newer DAA therapies that could be used in patients with renal impairment, including hemodialysis, without the need for dose adjustments. However, the regimen is contraindicated in patients with Child-Pugh class B or C cirrhosis. Prior to administering elbasvir/grazoprevir, patients with genotype 1a infection should be tested for the presence of NS5A resistance-associated substitutions (RASs) and NS3 protein polymorphisms. Preexisting NS5A polymorphisms that are associated with elbasvir resistance and lower SVR rates with the regimen in genotype 1a patients are found at positions M28, Q30, L31, and Y93.[233] Approximately 11% of genotype 1a viruses are estimated to harbor one of these polymorphisms prior to taking elbasvir/grazoprevir regimen. In the presence of one of the NS5A polymorphisms, ribavirin (weight-based) could be added to the regimen and the treatment course extended to improve the SVR rates. Of note, the polymorphisms do not affect the SVR rates in persons with genotype 1b virus infection. The polymorphisms in the NS3 protein, especially the Q80L polymorphism in genotype 1a virus, do not appear to affect treatment response and SVR rates. The other difference between the NS5A and NS3 polymorphisms appears to be the long persistence of the NS5A resistance mutations in the individuals after treatment.

Elbasvir/grazoprevir is overall well tolerated. From the large clinical trials, the most common adverse effects were headache, fatigue and nausea.[233,234] Approximately 1% of patients developed late aminotransferase elevations >5 times the upper limit of normal without associated bilirubin increases that resolved once the regimen was stopped. Aminotransferase monitoring at baseline and at week 8 of therapy (and at week 12, if the total duration is 16 weeks) is recommended.[232] The regimen should be discontinued if aminotransferase elevations are accompanied by other signs or symptoms of hepatic injury, such as jaundice, increased bilirubin, or

INR. The regimen is primarily metabolized through CYP3A, and grazoprevir is a substrate of OATP1B1/3 transporters. The coadministration of elbasvir/grazoprevir is contraindicated with potent inducers (e.g., rifampin, phenytoin, carbamazepine, Saint-John's-wort, cyclosporine), efavirenz and HIV protease inhibitors. Furthermore, coadministration of the regimen is not recommended with ketoconazole, nafcillin, modafinil and antiretrovirals (etravirine or cobicistat).

Ledipasvir/Sofosbuvir

Sofosbuvir (400 mg) is combined with ledipasvir (90 mg), a NS5A inhibitor, as a fixed-dose combination (Harvoni) that is administered as a single tablet with or without food.[213] The regimen is given with or without weight-based ribavirin, depending on the patient population, and is active against HCV genotypes 1, 4, 5, and 6. The levels of sofosbuvir and its metabolite might accumulate in the setting of severe renal impairment (eGFR >30 mL/minute/1.73 m^2); thus, the combination should not be used until further data are available. Otherwise, no dose adjustment is needed for mild or moderate renal impairment, or in the setting of moderate (Child-Pugh class B) or severe (Child-Pugh class C) hepatic impairment.

Harvoni is well tolerated, and the common adverse effects include fatigue, headache, nausea, and insomnia. With regard to drug interactions, ledipasvir is also a substrate of the P-gp drug transporter. Similar to sofosbuvir, ledipasvir should not be coadministered with potent intestinal P-gp inducers because its serum levels will significantly decrease. Ledipasvir absorption is affected by gastric pH. The coadministration of ledipasvir with acid-suppressing agents could increase the gastric pH levels and decrease its absorption. If the regimen needs to be taken with proton pump inhibitors, the proton pump inhibitor dose should not exceed a dose comparable to omeprazole 20 mg daily. If the regimen is given with H_2 receptor antagonists, such as famotidine 40 mg or equivalent, both drugs should be administered twelve hours apart.[226]

The resistance profile of Harvoni has been associated with several NS5A mutations that reduce the susceptibility to ledipasvir, such as Q30R, Y93H/N and L31M in subtype 1a virus and Y93H in subtype 1b virus.[235] The presence of NS5A mutations does not require adjustment of duration or dosing of the combination regimen. Further data are warranted to make any clinical adjustments.

Sofosbuvir/Velpatasvir

Another fixed-dose combination regimen (Epclusa) comprises of sofosbuvir (400 mg) with velpatasvir (100 mg), a NS5A inhibitor. It is coformulated as a single tablet and administered once daily for 12 weeks with or without ribavirin. The regimen is active against all HCV genotypes. No dose adjustments are needed for mild-to-moderate renal impairment, or in the setting of moderate (Child-Pugh class B) or severe (Child-Pugh class C) hepatic impairment. The same renal precautions apply to this combination regimen because it contains sofosbuvir. The commonly reported adverse effects include headache, fatigue, nausea, nasopharyngitis, and insomnia.[236]

Similar to sofosbuvir, velpatasvir is a substrate of the P-gp drug transporter. Therefore, coadministration of the regimen

---

with potent intestinal P-gp inducers can decrease both sofosbuvir and velpatasvir serum levels. The coadministration of Epclusa is contraindicated with anticonvulsants, anti-tuberculosis drugs, and Saint-John's-wort. Efavirenz can also significantly reduce the serum levels of velpatasvir and should not be coadministered. Velpatasvir is also an inhibitor of P-gp and thus may increase the absorption of P-gp substrates. Similar to ledipasvir, velpatasvir requires an acid gastric environment for optimal absorption. Proton pump inhibitors and H_2 receptor antagonists will increase the gastric pH levels, resulting in a decreased absorption of velpatasvir. If used with proton pump inhibitors, sofosbuvir/velpatasvir should be taken without food and 4 hours before omeprazole 20 mg or equivalent dose. The coadministration of amiodarone and sofosbuvir/velpatasvir is contraindicated because of severe bradycardia and cardiac arrest.[226] (See sofosbuvir section.)

Paritaprevir/Ritonavir/Ombitasvir plus Dasabuvir

The coformulated single tablet of paritaprevir/ritonavir/ombitasvir is given with dasabuvir, an NS5B non-nucleoside polymerase inhibitor. The regimen is called often referred to as PrOD (Viekira Pak, Viekira XR). PrOD can be taken with or without weight-based ribavirin, depending on the patient population, for the treatment of genotypes 1a and 1b without cirrhosis or with compensated cirrhosis. PrOD is also indicated in combination with ribavirin in liver transplant patients with any HCV genotype 1 subtype as long as hepatic function is normal and fibrosis is mild (Metavir score ≤2).[237] In contrast, the combination of paritaprevir/ritonavir/ombitasvir (Technivie) with ribavirin is approved for genotype 4 infections without cirrhosis. Technivie does not contain dasabuvir. Paritaprevir/ritonavir/ombitasvir, with or without dasabuvir, can be administered in HCV-infected patients with renal impairment. The administration of these regimens in patients with severe renal impairment (eGFR <30 mL/minute/1.73 m^2) has not been studied.[237] Dose adjustment for the regimens is not warranted for patients with mild (Child-Pugh class A) hepatic impairment. However, the regimens are contraindicated in patients with moderate-to-severe (Child-Pugh classes B and C) hepatic impairment. Hepatic decompensation was reported when the regimen is used, with or without dasabuvir, in patients with underlying cirrhosis.[238] Most of the reported cases occurred within 1 to 4 weeks of drug initiation, and some cases resulted in the need for liver transplantation or death.

PrOD is available in immediate-release and extended-release oral formulations.

For the immediate-release formulation (Viekira Pak), two combination tablets (each containing 12.5 mg ombitasvir, 75 mg paritaprevir, and 50 mg ritonavir) are administered once daily. Dasabuvir is administered with the regimen as a single 250-mg tablet twice daily. For the extended-release formulation (Viekira XR), three tablets (each containing 8.33 mg ombitasvir, 50 mg paritaprevir, 33.33 mg ritonavir, and 200 mg dasabuvir) are administered once daily with ribavirin (weight-based dosing) in two divided doses with food. PrOD regimens should be taken with food and are generally well tolerated. The most commonly reported adverse effects in the trials that used the PrOD regimen with ribavirin included nausea, pruritus, insomnia, diarrhea, and asthenia.[239,240] Fatigue and headache were the most common side effects and may be attributable to the ribavirin component. Decreases in the hemoglobin level, by 2 to 2.5 g/dL, were also observed in patients taking regimens with ribavirin. The incidence of severe anemia (hemoglobin <8 g/dL) is uncommon.[239,240]

The components of PrOD are both substrates and inhibitors of CYP450 enzymes. The coadministration of paritaprevir/ritonavir/ombitasvir and dasabuvir is contraindicated with anticonvulsants, rifampin, Saint-John's-wort, oral contraceptives containing ethinyl estradiol and salmeterol.[237] Close monitoring and dose adjustments of certain drugs (e.g., HMG-CoAs, cyclosporine, tacrolimus, and antiarrhythmics) are recommended when given with the PrOD regimen.

The use of paritaprevir, ombitasvir, and dasabuvir can select for resistance mutations in NS3, NS5A, and NS5B, respectively, which will reduce the activity of a particular antiviral agent. In the clinical trials, the common resistance mutations that have emerged and/or caused treatment relapse among the genotype 1a infections were D168V in NS3, M28A/T/V and Q30E/K/R in NS5A, and S556G/R in NS5B.[239–242] In contrast, there were not many virologic failures in patients with HCV genotype 1b infection.

Future Treatment Options[243]

Several agents are currently under investigation for HCV genotype 1 infection, including voxilaprevir, ABT-493 plus ABT-530, and MK-3682 and MK-8408. Voxilaprevir is an investigational NS3/4A protease inhibitor currently studied in a coformulated combination with sofosbuvir-velpatasvir. This triple combination pill is intended to be used as short-duration treatment and as salvage therapy for DAA treatment failures.

The ABT-493 (NS3/4A protease inhibitor) plus ABT-530 (NS5A inhibitor) coformulated combination has pangenotypic activity currently under study as both an 8-week regimen for genotype 1 patients without cirrhosis and a 12-week salvage regimen for DAA-experienced patients.

The MK-3682 (NS5B inhibitor) plus MK-8408 (second generation NS5A inhibitor) are being studied in a variety of triple combinations with either grazoprevir or elbasvir as an 8-week regimen in genotype 1, 2, or 3 infection.

HEPATITIS D VIRUS

Virology and Epidemiology

HDV is a small, single-stranded circular RNA animal virus (36 nm) that is similar to defective RNA plant viruses (Table 80-1).[244–246] Between 15 and 20 million persons are infected with HDV globally, particularly in the Mediterranean basin, the Middle East, Central and Northern Asia, West and Central Africa, the Amazon basin, Colombia, Venezuela, Western Asia, and the South Pacific. [244–246] Vaccination for HBV significantly reduces the incidence of HDV. However, immigration from endemic areas, increased IV drug use, sexual practices, and body modification procedures have resulted in an increase in HDV prevalence in some regions. In the United States, an estimated 7,500 HDV cases occur annually.[247,248] The prevalence of HDV is greatest among persons with percutaneous exposure (e.g., injection drug users) and hemophiliacs (20%–53% and 48%–80%, respectively) and may be affected by additional factors such as duration of infection.[247,248] The modes of transmission of HDV are similar to those reported for HBV infection. Thus, HDV clearly represents a potential infectious hazard to patients susceptible to HBV and those who are chronic HBV carriers. Generally two major patterns of infection occur with HBV: coinfection and superinfection. Because infection by HDV requires the presence of active HBV, preventing HBV infection will prevent HDV infection in a susceptible patient.[248,249]

Pathogenesis

Limited data suggest that HDV antigen and HDV RNA are cytotoxic to hepatocytes; however, the immune response may also be important.[248,249] Furthermore, several autoantibodies associated with chronic HDV infection may play a role in propagating liver disease and could partially explain the differences in disease severity observed in patients with HDV plus HBV compared with those with HBV alone.

Diagnosis and Serology

Measuring HDV RNA (by RT-PCR) for HDV RNA confirms the presence of HDV and is currently the most accurate diagnostic tool available.[248,249] ELISA and radioimmunoassay tests for IgM anti-HDV are also commercially available. Measurement of anti-HDV is generally not useful for early diagnosis because detectable antibody levels are usually achieved late in the clinical course of the infection. Anti-HDV IgM is detectable before anti-HDV IgG in acute HDV coinfection and is diagnostic for acute HDV infection. Anti-HDV IgM levels are not sustained in self-limiting HDV infection but may persist in patients with chronic HDV infection. Also, anti-HDV IgM does not distinguish coinfection (HBV and HDV acquired simultaneously) from superinfection (HDV acquired in chronic HBV carrier).

Differentiation between coinfection and superinfection is made by the presence or absence of anti-HBc IgM. In acute coinfection, serum anti-HDV IgM and HDV RNA appear together with anti-HBc IgM, whereas in patients with superinfection, HDV markers are present in the absence of anti-HBc IgM. The presence and titer level of anti-HDV, in the case of persistent infection, also correlate with the severity of disease. Titers of anti-HDV IgG greater than 1:1,000 indicate ongoing viral replication.

HDV antigen is present in the serum in the late incubation period of acute infection and lasts into the symptomatic phase in up to 20% of patients. Because this antigen is transient, repeat testing may be required to detect its presence. HDV RNA is an early marker of infection in patients with both acute and chronic HDV infection.[248,249] HDV RNA is detectable in 90% of patients during the symptomatic phase of HDV infection. HDV RNA levels are not detectable after symptomatic resolution but remain elevated in chronic infection.

Natural History

Coinfection with HDV and HBV is correlated with a higher risk of severe or fulminant liver disease.[249,250] The rate of chronic disease after coinfection with HDV is similar to that of HBV infection alone, whereas superinfection with HDV is linked to a high rate of chronicity; however, the clinical course may be variable. Approximately 15% of patients superinfected with HDV develop rapidly progressive disease with hepatic decompensation (e.g., cirrhosis) within 12 months of the infection. Another 15% of patients have a benign course of illness. Most patients (70%) have a slow progression to cirrhosis, depending on age, IV drug use, and level of viral replication.[249] Finally, HBsAg-positive, HBeAg-positive patients who are superinfected with HDV are more likely to develop fulminant disease compared with those who are HBsAg-positive with anti-HBe and who are superinfected and develop chronic disease.[249,250]

Prevention

Hepatitis D virus replication is dependent on HBV replication; therefore, successful immunization with HBV vaccine also prevents HDV infection.[244–246] No immunoprophylactic therapies are available for patients with chronic HBV infection who are also at risk for superinfection with HDV. Prevention of HDV superinfection is based on behavioral modification, such as the use of condoms to prevent sexual transmission and needle exchange programs to minimize transmission by IV drug use.

Treatment

The goal of treatment is to eradicate HDV along with HBV. HDV is eradicated when both serum HDV RNA and HDV antigen in the liver become persistently undetectable. Notably, it is only when HBsAg clearance has taken place that complete clinical resolution occurs. Supportive care is the general strategy used to treat HDV infection. Because the development of FHF is more frequent with HDV infection, close monitoring for evidence of severe liver failure is warranted. Liver transplantation is the treatment of choice for patients with fulminant or end-stage liver disease after HDV infection. In patients with chronic HDV infection, antiviral therapy has been disappointing.[251–254]

In patients with decompensated cirrhosis caused by HDV, liver transplantation is the most appropriate intervention because IFN may precipitate hepatic decompensation.[251–254] The presence and amount of HBV DNA before transplantation is the most significant outcome marker, often predicting the post-transplant reinfection rate. Patients who receive a liver transplant for chronic HDV infection have a lower incidence of post-transplant HBV infection than do those with HBV infection alone (67% vs. 32%, respectively).[253,254] This is thought to be related to an inhibitory effect of HDV on HBV replication. Furthermore, 3-year survival is higher for patients with HDV cirrhosis than for patients undergoing transplantation for HBV cirrhosis alone (88% vs. 44%, respectively) and is similar to patients having liver transplantation for other indications.[117–119]

HEPATITIS E VIRUS

Virology, Epidemiology, Transmission, and Pathogenesis

HEV is an icosahedral, nonenveloped virus of the Hepeviridae family (Table 80-1). The HEV genome is a single-stranded polyadenylated RNA and, unlike HAV, has an RNA genome that encodes for NS proteins through overlapping open reading frames.[255,256] HEV sequences have been classified into four genotypes (1, 2, 3, and 4). Genotype 1 consists of epidemic strains in developing countries; genotype 2 has been found in Mexico; genotype 3 has been associated with acute cases of hepatitis and with domestic pigs in the United States, European countries, and Japan; and genotype 4 has been found in Asian countries.[257–260]

HEV occurs in endemic areas such as Africa, Southeast and Central Asia, Mexico, and Central and South America as both epidemic and sporadic infections.[258,259,261,262] Sporadic infections also occur in nonendemic areas and are usually associated with travel into areas of endemicity. The attack rate (the percentage of exposed patients who become infected) of HEV is low compared with HAV (1% vs. 10%, respectively). In endemic areas, outbreaks usually occur between 5 and 10 years apart and are often associated with times of heavy rainfall, after floods or monsoons, or after the recession of flood waters.[260–262] The overall case fatality rate for the general endemic population is 0.5% to 4%, whereas for reasons unknown, pregnant women have a much greater case fatality rate of 20%.[263] In particular, the fetal complication rate is increased, especially if the infection occurs in the third trimester of pregnancy. The frequency of death in utero and immediately after birth is also greater than that seen with acute hepatitis of other causes.[263]

Transmission of HEV is via the fecal–oral route, and the most common source of transmission is ingestion of fecally contaminated water.[261,262] Poor climactic conditions in conjunction with inadequate personal hygiene and sanitation have led to epidemics of HEV infection. Additional routes of transmission include consuming raw or undercooked meat of infected animals such as boar or deer and domestic animals such as pigs, vertical, and bloodborne transmission.[258,259]

Interference with the production of cellular macromolecules, alteration of cellular membranes, and alteration of lysosomal permeability are some of the proposed mechanisms of hepatic injury.[257,259] In addition, immune-mediated mechanisms are believed to be responsible for lysis of virally infected hepatocytes by direct lymphocyte cytotoxicity or antibody-mediated cytotoxicity.

Diagnosis

Initial assays for detection of anti-HEV used electron microscopy to detect HEV antigen on the surface of HEV particles in stool and serum and immunohistochemistry to detect the antigen in liver tissue.[257,259,260] Fluorescent antibody-blocking assay is currently used to detect anti-HEV reacting to HEV antigen in serum, but although highly specific, this assay lacks sensitivity (50%) in acute HEV infection.[257,259,260] Additional cloning and sequencing of HEV has led to the development of Western blot assays and ELISA that detect anti-HEV by using recombinant expressed proteins from the structural region of the virus. RT-PCR has also been used to confirm the diagnosis of HEV by detecting HEV RNA from serum, liver, or stool.[257,259,260] Clinically, HEV is a diagnosis of exclusion.

Clinical Manifestations and Natural History

Typical HEV clinical symptoms include jaundice, dark urine, tender and enlarged liver, elevated liver enzymes, abdominal pain, nausea, vomiting, and fever. Protracted coagulopathy and cholestasis have also been reported in more severe cases, possibly related to genotype 4.[257–259] Two phases of illness exist, including a prodromal and preicteric phase. Peak serum aminotransferase levels reflect the onset of the icteric phase and generally return to baseline by 6 weeks.[257–259] Stool is often positive for HEV RNA at the onset of the icteric phase and persists for an additional 10 days beyond this period. Viral shedding may occur for up to 52 days after the onset of icterus. Detection in the serum occurs during the preicteric phase, before detection of virus in the stool, and becomes undetectable after the peak in aminotransferase activity. Because HEV RNA is not detectable in the serum during symptoms, diagnostic tests using HEV RNA have limited utility, and a correlation between PCR detection and infectivity has not been observed. Serologically, HEV IgM becomes detectable before the peak rise in ALT, whereas antibody titers peak with peak ALT levels and subsequently decline. In most patients, HEV IgM is present for 5 to 6 months after the onset of illness. HEV IgG appears after HEV IgM and remains detectable for up to 14 years after acute infection; however, the duration of protective immunity has not been fully elucidated.[257–260]

In nonfatal cases, acute HEV hepatitis is followed by complete recovery without any chronic complications. There is protection from reinfection; however, the duration of protection is variable.

Prevention and Treatment

No immunoprophylactic measures exist for HEV disease, and effective prevention strategies are dependent on improved sanitation in endemic areas. Travelers going to endemic areas should be educated regarding the risks of drinking water, eating ice, or eating uncooked shellfish or uncooked and peeled fruits and vegetables. Drinking water should be boiled to inactivate HEV. No vaccines or postexposure prophylaxis treatments are currently available to prevent HEV infection.

SUMMARY

Viral hepatitis continues to be a significant worldwide infectious disease. To date, prevention strategies through universal vaccination are the most efficient methods for minimizing the incidence of HAV, HBV, and HDV coinfected with HBV. Patient education with respect to the common ways of spreading these infections may also result in behavioral modifications that reduce the overall incidence of infection. Once HBV and HCV progress to chronic infection, more efficacious and better-tolerated antiviral therapies are needed to treat these infections. Similarly, therapeutic modalities that reduce the progression of these diseases are necessary to prevent end-stage liver disease and the development of additional complications (encephalopathy, intractable ascites, coagulation disorders, and HCC). As a better understanding of viral replication is established, as well as appropriate models for study, new therapeutic agents are becoming available. Furthermore, viral kinetics and genomic-based approaches may optimize responses to drug therapies, especially in HCV-infected patients. The economic impact and quality of life of these patients remain to be fully elucidated.
